

BRITISH MEDICAL JOURNAL

THE JOURNAL OF THE BRITISH MEDICAL ASSOCIATION

Edited by
NORMAN GERALD HORNER, M.D., F.R.C.P.

Assisted by
HUGH CLEGG, M.B., M.R.C.P.

VOLUME II 1941
JULY TO DECEMBER

KEY TO DATES AND PAGES

The following table, giving a key to the dates of issue and the page numbers of the BRITISH MEDICAL JOURNAL and SUPPLEMENT in the second volume for 1941, may prove convenient to readers in search of a reference.

Serial No.	Date of Issue	Journal Pages	Supplement Pages
4200 ..	July 5 ..	1 - 38	1 - 2
4201 ..	" 12 ..	39 - 74	3 - 6
4202 ..	" 19 ..	75 - 108	7 - 8
4203 ..	" 26 ..	109 - 148	9 - 14
4204 ..	Aug. 2 ..	149 - 186	15 - 18
4205 ..	" 9 ..	187 - 216	19 - 20
4206 ..	" 16 ..	217 - 254	21 - 28
4207 ..	" 23 ..	255 - 292	29 - 32
4208 ..	" 30 ..	293 - 322	33 - 38
4209 ..	Sept. 6 ..	323 - 364	39 - 44
4210 ..	" 13 ..	365 - 392	45 - 48
4211 ..	" 20 ..	393 - 428	49 - 58
4212 ..	" 27 ..	429 - 464	59 - 70
4213 ..	Oct. 4 ..	465 - 496	71 - 74
4214 ..	" 11 ..	497 - 532	75 - 76
4215 ..	" 18 ..	533 - 568	77 - 80
4216 ..	" 25 ..	569 - 600	81 - 84
4217 ..	Nov. 1 ..	601 - 640	85 - 88
4218 ..	" 8 ..	641 - 680	89 - 90
4219 ..	" 15 ..	681 - 716	91 - 94
4220 ..	" 22 ..	717 - 758	95 - 96
4221 ..	" 29 ..	759 - 794	97 - 100
4222 ..	Dec. 6 ..	795 - 836	101 - 104
4223 ..	" 13 ..	837 - 864	105 - 108
4224 ..	" 20 ..	865 - 896	109 - 112
4225 ..	" 27 ..	897 - 932	113 - 116

Annotations (continued):

- Toddlers, aggregation of, 91
- Traffic offenders, 234
- Tuberculosis: Treated by arrest of lung movement, 271—In Wales, grim outlook, 587—Chemotherapy for, 856
- bovine, in Australia, 734
- Ulceration, streptococcal, around wounds, 553
- Urticaria, solar, 918
- U.S.S.R., health in, 445
- Vaporizers, Oxford anaesthetic, 204
- Viruses and infection through skin, 587
- Vitamin B₁ deficiency, 22
- B₂ (adernin), 166
- E, international standard for, 553
- P and capillary resistance, 517
- War: American doctor speaks on, 483—And common health, paradox, 813
- Welch toxins, physiological action of, 127
- X-ray injury again, 165
- X rays in treatment of inflammations, 700

Annual Review of Physiology, vol. 3, 407

- Anthraxis, preventive measures, 426
- Anthrax, cutaneous, arsenicals and sulphapyridine for (I. M. Davidson), 725 (O)
- Anthropologist, memoirs of, 512
- Antigens, bacterial, chemical nature of, 382
- Antiscorbutics, root vegetables as (D. M. Mathews and A. L. Bacharach), 226 (O)
- Antiseptic, intestinal, sulphanilguanidine as (leading article), 514
- Antitoxins, fifty years of, 413
- Apparatus, high-frequency, 833
- Appendicitis, acute, blood sedimentation rate in, 626
- Appendix at angulated in congenital hernial sac in infant (T. O'Neill), 87
- APPLETON, Arthur B.: Flat-foot in Army, 355
- J. L. T.: Control of Pain in Dental Practice, 162
- Apte, Capt. S. S., death of, 929
- Aqueous and glaucoma (leading article), 515: correspondence on, 593
- ARCHIBALD, Roy McL.: Students and curriculum, 711
- Archiv für Schiffs- und Tropen-hygiene, title changed, 171
- ARMSTRONG, John: Cardiac arrest during anaesthesia, 364
- Katherine F. (and others): Handbook of First Aid and Bandaging, 513
- Army. See Services
- Arsenicals and sulphapyridine for cutaneous anthrax (I. M. Davidson), 725 (O)
- Arteriosclerosis: Exercises for, 108—Of extremities, thrombosis in (E. D. Telford and H. T. Simmons), 575 (O)
- Arthritis: Review of book on, 547—Gold in treatment of, 882
- rheumatoid, stabbing heel pains in, 716, 836, 864
- Asepsis, new rules for (leading article), 698
- Asphyxia, traumatic (E. K. Gardner), 545
- Association, American Medical: President elected, 254—Medal presented, 254
- of Anaesthetists: Officers elected, 678
- British, for Advancement of Science: Scientists and post-war relief, 516
- Hospitals: Liaison committee, 344
- Annual meeting, 664—Meeting of Scottish Branch, 746—Regional hospital services, 919

ASSOCIATION, BRITISH MEDICAL:

- Bristol Division. Casualty surgery in air raids, 131
- Committee, Mental Health: Report, 276; leading article on, 269; price of, 390
- Hospitals: Liaison committee, 344
- Jamaica Branch, cable from, 622
- Meetings at Headquarters, 413
- Report of special committee on industrial medical practice, 783

Association, British Medical Students, 32, 278—

- Students and curriculum, 629
- Orthopaedic: Summer meeting, 351
- Canadian Tuberculosis: Annual meeting, 23
- Central, for Mental Welfare. Report, 173
- of Clinical Pathologists: Meeting, 315
- Czechoslovak Medical, in Great Britain: Medical reception, 740
- Grenfell: Postcards, 716
- Industrial Medical Officers: Annual meeting, 745
- Hospital, 716—Conference in London, 819
- Mental After-Care: Report of employment department, 205
- Royal Medico-Psychological: 100th annual meeting, 172
- Sanitary, of Scotland: Annual congress, 459
- of Special Libraries and Information Bureaux: Library publications, 108
- Temperance Collegiate: Confirming the Facts, 200

Autopsy, review of book on, 52

- Atrophy, compensatory, 126
- Aviation. Lord, memorial to, 883
- Motor Company. New medical dept., 883
- Aviation: Doctors in, 35—Annual report on public health in N.W., 304—Serum research in, 314—Lawyer appointed, 390—Bovine tuberculosis in, 711
- Avian. Before 1900, 61—Poliovirus serum 744, 756

- AVERY, Harris: Lack of calcium, 285
- Aviation, medicine and (leading article), 879
- Avitaminosis. See Vitamin
- AYTOUN, John M.: Anatomical nomenclature, 210

B

- Baby feeding, simplified formula for, 38
- Week, National, 28
- BACHARACH, A. L. (and D. M. MATHEWS): Root vegetables as antiscorbutics in infant feedings, 226 (O)—Vitamin E in neuromuscular disorders, 709
- Bacillus, Flexner. See Dysentery, Flexner
- BACON, Harry E.: Anus-Rectum-Sigmoid Colon: Diagnosis and Treatment, 2nd ed., 547
- Lionel J.: Trichiniasis in Birmingham, 909 (O)
- Bacteria from wounds enclosed in plaster, 268, 387
- Bacteriology: Review of book on, 51—Of air-raids wounds within 48 hours of infection (E. T. C. Spooner), 477 (O)
- diagnostic, 359
- Bacteriophage, treatment with (leading article), 409
- BADENOCH, A. G.: Colds in air-raid shelters, 392
- Bagot, Surg. Lieut. Frederick, reported missing, 792
- BAILEY, Hamilton: Ether convulsions, 32—Cardiac massage for impending death under anaesthesia, 84 (O): correspondence on, 175, 243, 356, 423
- Baldwyn, Flying Officer Antony Fleming, reported missing, 792
- Bale, Rosa, obituary notice of, 755
- BALLON, Leslie: "Perfect sight without glasses," 562; correction, 600
- Bandaging: Looped-cap system, 339—Avoiding painful removal of adhesive bandages, 364
- BANKS, H. Stanley: Planning in fever service, 922
- Bannister, Freda B., Dr. F. B. Pratt changes name to, 464
- Banting, Sir Frederick Grant, memorial to, 290
- Bar, medical men called to, 794
- BARACH, Alvan L.: Treatment of tuberculosis by arrest of lung movement, 271
- BARBER, C. H.: Penetrating wounds of abdomen, 284

Preparations and Appliances:

Bacteriological specimens from wounds treated by closed-plaster method, improved method of obtaining, 268
 Bandaging, eye and mastoid: looped-cap system, 339
 Cannula, new type of, 878
 Cystotomy, suprapubic, bougie for, 730
 Electric heaters in surface shelters, 480
 Eyes, contaminated, device for washing, 480
 Foreign bodies in tissues, electric probe for location of, 616
 Glucose saline, intramuscular drip, 616
 Laryngoscope, improved, 914
 Mobile unit, useful addition to equipment of, 513
 Nicorbin tablets, 654
 Orgakine, 89
 Ostelin capsules, high-potency, 654
 Pentothal sodium solutions, apparatus for administration of, 18
 Plaster casts, removal of, 772
 Prostate, endoscopic resection of: improved technique, 583
 Rotenone lotion for scabies, 201
 Siccolam, 772
 Sling, self-fitting, 810
 Smith-Petersen nails, new director for inser of, 549
 Speculum, useful, 696
 Splint, Böhler-Braun leg, single or bilateral.
 ——— Thomas, extension foot-piece and sup; for use with, 422

Preparations and Appliances (continued):

Stopecock, three-way, improved, 122
Transfusion panner, 230
Urethra, ruptured, metal guides for rubber catheters for use in retraining, 543
Vem-zecker, easily made, 730

Prescribing: Wartime, 602—Pruning the prescription (leading article), 854

THE TREATMENT OF BURNS AND WOUNDS BY THE ENVELOPE METHOD

BY

JOHN BUNYAN, *Surgeon Lieut.-Commander (D), R.N.V.R.*

(WITH SPECIAL PLATE)

Introductory Remarks

The outbreak of war has naturally resulted in much research into the treatment of burns and wounds. Experience has led to the modification and even rejection of some previously accepted methods of treatment. The most notable incident has been the discovery of the disasters that may follow the application of tannic acid to the hands and face. Some of the therapeutic advance up to date has been of an empirical, trial-and-error type, and has left much room for improvement. The scientific theoretical aspect of the question is still, it is suggested, capable of further development.

My interest in inflammatory disorders and wounds of the mouth led me to form certain hypotheses and opinions on the problem of the local treatment of inflammatory conditions in general. My theoretical views were as follows:

First, sound healing of the tissues is assisted by gentle but thorough cleansing, with removal of dead tissue and avoidance of irritant applications, together with every encouragement to the physiological outpouring of serum and leucocytes into the injured area. This assistance is, of course, strengthened by any bactericidal treatment that can be given without damage to living cells and by the prevention of secondary infection.

Secondly, it is desirable that any treatment given should be painless, and, if possible, alleviate existing pain, and that it should reduce to the minimum the necessity for general anaesthesia. It would be a great advantage if the local treatment permitted the active and passive movements of the injured part at all times.

Thirdly, a local treatment of burns should have the following qualities: it should not aggravate primary shock; it should diminish and inhibit the loss of body fluid from the burnt area; it should reduce toxæmic shock from the absorption of protein breakdown products and bacterial toxins; and it should disinfect without irritating or damaging the healing tissues.

In the past less success than was hoped for has followed the treatment of burns and wounds because irritating, destructive antiseptics were used, which killed tissue as well as organisms. At the same time the type of frequently changed dressing, conventionally applied, gave rise to pain on removal, to destruction of newly formed tissue to which it was adherent on each removal, and to immobility and disuse of the part to which it was applied. Frequent changing of a dressing introduced the inescapable danger of secondary infection from such sources as droplets from the nose and mouth of other individuals or from ward dust.

To obtain improvements in the local dressing of burns and wounds it is therefore desirable to employ a dressing which may be kept applied without changing for a considerable period—preferably during the whole course of treatment. The dressing should be flexible, frictionless, bland to the tissues, and, if possible, transparent, in order that progress may be constantly observed. The dressing should combat bacterial contamination and be watertight, so that fluids applied to the injured area would be confined within bounds.

Apart from avoiding the necessity for changing, the dressing should permit free movement if this is desirable, and permit constant drainage and cleansing of the affected area.

The Therapeutic Agent

In attempting to devise an improved form of dressing to meet the above-mentioned requirements, the form of solution to be applied to burns and wounds was attended to first. It was desired to find one which was non-toxic, non-irritant, capable of dissolving dead organic matter, able to encourage transudation of serum and cells, and to exert some bactericidal power in concentrations that would be harmless to healing tissue, and which would be easily obtainable anywhere and at any time.

From personal clinical experience, and from literature on the subject, it was decided that sodium hypochlorite solutions most fulfilled these desiderata, and that the hypochlorite solution produced by electrolysis of sodium chloride was the best preparation, having the least irritant action. The following are a few important points in the manufacture of hypochlorite solutions.

First, sodium hypochlorite solution can be made by a chemical process. Chlorine gas can be passed through dilute caustic-soda solution at suitably low temperatures. The reaction is as follows:

In solutions prepared this way sodium hypochlorite and sodium chloride will usually be found in equal quantities, but there will always be an excess of caustic soda remaining in solution.

Sodium hypochlorite solution can also be made in an indirect chemical manner by the use of bleaching powder. The danger of causticity is present in this method also, as exemplified in the case of liq. sod. chlorinatae (B.P.C.). In Dakin's solution causticity is reduced by the addition of boric acid, but some of this is absorbed by the tissues, so that free soda is always present. Calcium hypochlorite solution made from bleaching powder is also combined with boric acid to form eusol.

$$2\text{NaOH} + \text{Cl}_2 = \text{NaOCl} + \text{NaCl} + \text{H}_2\text{O}.$$

* The word "dissolve" as applied to the removal of dead organic matter is not used in its true chemical sense, but is employed to describe the undoubted washing away of stale exudate and sloughs.

Different shapes and sizes are being tried out, and as the method develops it is hoped to be able to provide a simple means of effectively isolating any part of the body.

(b) *Other Apparatus:*

1. Special trolley for use in hospital.
2. Containers for hypochlorite solution, of glass or vulcanite.
3. Thermometer.
4. Rubber tubing and clips (sterile).
5. Glass cannula and vulcanite roses (sterile).
6. Higginson's syringe (sterile).
7. Waste container (bucket or bowl).
8. Silk sheeting.

(c) *Method of Application of Envelopes.*—See Treatment of Burns.

Technique of Treatment: (i) Preparation of Sodium Hypochlorite

Electrolytic sodium hypochlorite can be made with a small electrolytic cell, as used in modern water purification, producing three pints of 0.6% NaOCl (unstabalized) from 10% NaCl solution in six hours. With a larger plant considerable quantities of NaOCl can be produced as required. However, if this plant is not available, the simplest way to obtain as much sodium hypochlorite as required, in a standardized stabilized solution, was found to be to use "milton" solution, which is 1% NaOCl, standardized and stabilized, and which has been and is being kindly supplied by Messrs. Milton Proprietary Ltd. Since this concentration is a very convenient one for using as a stock solution, it has been decided to refer always to a 1% solution of sodium hypochlorite, electrolytically produced, as E.S.H., so that when we talk of a 5% solution of E.S.H. we mean 1 part of 1% electrolytic sodium hypochlorite to 20 parts of water. This 1% solution of E.S.H. has been used in all my experiments, and appreciation of the assistance given by the manufacturers must be expressed.

Various concentrations of E.S.H. were employed for different purposes. It should be remembered that solutions of E.S.H. above 5% in water are hypertonic, those of 5% almost exactly isotonic, and those below 5% hypotonic. The following guide to the concentration of E.S.H. for various purposes is given.

First, when gross sepsis is present, or dead tissue such as sloughs, scabs, etc., has to be removed, then E.S.H. in strengths up to 50% in water may be used. A concentration of 20% is a good average one. Hypertonic solutions assist the diminution of oedema.

Secondly, when the primary object of thorough cleansing has been attained, and daily irrigation is instituted, to remove stale exudate and to control infection, this daily irrigation should be carried out with a 5% solution. If the skin is very sensitive, or if healing is progressing rapidly, then the concentration may be reduced to 2½%. When there is no infection, or the infection is so slight as to be almost negligible, and stimulation of healing is the main objective, the 1% solution is adequate.

Temperature control is important. The solution should be kept at body heat. It should be made a rule that it be kept at 100° F., except that the initial irrigation done under analgesia or anaesthesia may be carried out at 110° F. Patients are extraordinarily sensitive to slight temperature variations, and great care should be exercised to ensure that the solution is at 100° F. exactly.

(ii) *Treatment of Burns*

The general treatment of shock, etc., need not be detailed here. It may be mentioned that when a general anaesthetic is necessary for the débridement and dressing of burns it need only be a light one. Various forms of anaesthesia and analgesia have been employed, including intravenous morphine, omnopon, and barbiturates. I have been impressed by the advantages of a vaporizer for delivering warm ether vapour of any desired concentration,

devised by the Nuffield Department of Anaesthetics, Oxford: anaesthesia, and even analgesia, have been most satisfactory, and the patients have had no ill effects from their use.

There is much confusion regarding the best method of first-aid treatment for burns, and guidance has hitherto taken the rather negative form of instruction to do nothing. Since some time may elapse before admission to hospital it is felt that the application of packs of E.S.H. to the burn is a considerable advantage—the relief of pain and the practical disinfection, together with prevention of fluid loss, are of great importance. Packs may be applied anywhere quite easily, and cannot possibly do any harm.

First-degree burns may be bathed in 50% E.S.H. for ten minutes, after which the concentration is lowered to 10% for ten minutes. The area is dried and then covered with adhesive plaster. Relief of pain is found to be immediate, and after twenty-four hours there will be little sign left of the burn. Second- and third-degree burns may be classed as either primary or secondary. Primary burns are those that arrive for treatment without having received any attention other than first aid.

It must here be noted that it has been found most difficult to decide at first whether a burn is a bad second or of actual third degree. There can be no doubt that many second-degree burns progress to third degree because of sepsis or trauma, and it is felt that the use of this method will enable treatment to be carried out without the possibility of any harm until the degree of the burn is established. By then any form of treatment may be undertaken without having run the risk of the catastrophes associated with the treatment of deeper burns.

A patient with a second- or third-degree burn is pre-medicated and anaesthetized as may be necessary, and local treatment is begun. When the blisters are unbroken the area is washed over on the surface with 20% E.S.H. at 100° F. Blisters should then be aspirated with a fine needle and some 10% E.S.H. injected into them. This should be left in for five minutes, and then withdrawn by syringe and needle, and the skin pressed down flat with a dry dressing. When the skin is broken the dead skin should be cut away under a stream of E.S.H., bathed for ten minutes in a 10% solution, and covered with a sheet of the special coated silk sealed at the edges with adhesive.

To deal with large burnt areas a suitable silk envelope, previously sterilized, is fitted. E.S.H. in the strength described is run through the envelope, washing all the affected area. The envelope is drained well and then inflated with oxygen, the inlets being sealed with adhesive tape or rubber-covered clips. Next day the irrigation routine begins: 5% E.S.H. is employed at 100° F., and is run through the envelope over the affected area for twenty minutes. This procedure is carried out three times a day, draining thoroughly for half an hour after the irrigation and then inflating with oxygen. A sheet of coated cotton is placed under the affected part to prevent wetting of the bedclothes, and the tube from the outlet is run into a basin, all this being explained in the directions for applying the envelopes.

In the case of hands the envelope may be filled with E.S.H. for the last ten minutes of irrigation to encourage the patient to move the fingers and wrist. A jet of E.S.H. from a Higginson syringe through the inlet opening may be used to remove sloughs and exudates.

In the case of third-degree burns of the hand and forearm an arm-bath is filled with E.S.H. solution up to a concentration of 20%. The more cleansing that has to be done the stronger should be the concentration. A jet from a Higginson syringe should be employed to scour-irrigate the limb, using the solution in the arm-bath. Dead skin should be removed almost to the margin of the burn. It should not

be removed right up to the edges, to its junction with normal skin, as this may result in subsequent pain. No scrubbing should be employed. Hosing with the Higginson syringe should be continued until spontaneous haemorrhage takes place and the burnt area becomes covered with a firm shiny fibrin coagulum. If profuse bleeding occurs no anxiety need be felt, since it has been found that it will cease spontaneously when the envelope is applied. Definite depilation-points should be twisted or ligatured. Axillary depilation and nail-cleansing should be carried out.

The burned area is now covered with coated silk sheeting and dried outside this with sterile towels, the envelope being slipped into position over the limb and outside the sheeting. The latter is withdrawn from inside the envelope, the normal skin beneath the seal of the envelope is dried with aether meth., and the seal is closed. A small quantity of E.S.H. (of concentration previously described) is then run over the whole limb, the envelope is drained, oxygen is run in, and the inlets are sealed. Routine thrice-daily irrigation is now maintained for as long as necessary, as previously outlined.

These details apply equally to burns of the legs; but there are certain practical points of importance in addition so far as the legs are concerned. It is convenient to lay the patient on a length of coated cotton sheeting spread out on a table (e.g., an operating table), the sides of the sheeting being raised up by any suitable device. The lower end of the sheeting is formed into a trough leading to a receiver at the foot of the table. The table is slightly tilted to allow the fluid to run into the receiver. The whole of the affected area is then sprayed with E.S.H. of suitable concentration. The whole leg may be enclosed in an envelope, but if this is done care should be taken to see that the foot is thoroughly cleansed. In burns involving the upper thigh pubic depilation is necessary, and should there be no room between the perineum and the burn for the envelope to be sealed, then its use should not be attempted. Burns of this nature need treatment in a "perineal bath," which has proved of great value in the treatment of burns and wounds involving this area. Otherwise, primary third-degree leg burns are treated exactly as those of the hands and arms.

Secondary third-degree burns are those which have been subjected to treatment beyond that of mere first aid and which have failed to heal and have become infected. The technique of their treatment is similar to that of the primary type, but cleansing must be very thorough. When supuration is present under the tan the latter should be dissected away to the healthy margins. Any obviously necrotic subcutaneous tissue should also be removed. The dissection should be carried out under a stream of E.S.H. up to a 20% concentration, and a thorough scour-irrigation should be given for twenty minutes after the removal of the tan. The envelope is then applied and routine thrice-daily irrigation instituted as previously described. Healing usually proceeds rapidly in third-degree burns subjected to this treatment, and at the end of ten days, and sometimes earlier, any areas needing it can safely be skin-grafted.

Where the face and head are burnt, the initial cleansing is done in the normal manner, except that 10% E.S.H. is used. This is sprayed on through a vulcanite rose, with the patient bending his head over a wash-basin or bowl. If a patient cannot leave his bed he lies back with a silk sheet attached around his neck and beneath his head, forming a chute through the head of the bed into a pail. A cylindrical envelope which has slits for his eyes, mouth, and nostrils is then applied. In the two cases treated in this manner the patients have been free from pain, oedema of the eyelids has been reduced very rapidly, and the eyes have shown no signs of any irritation. Where necessary the eyes are washed with 1% E.S.H. solution, after which drops of sterile paraffin are inserted. Immediate skin-

grafting may be carried out in many cases or may be deferred for a few days to permit some granulation.

Burns of the limbs may be complicated by the presence of compound fractures. When this is the case it is suggested that treatment might be as described, and plaster or other splinting be applied outside the envelope. In some cases splinting is best fitted (if it is small) inside the envelope.

It has been noticed that most of the burns suffered by small children are extensive and are not capable of being treated in one or other of the limb envelopes. Small vests have been made for covering burns of the upper part of the body, and a nightgown of coated silk with hood has been fitted so that the whole of the child is enclosed, leaving sufficient length from the feet to form a trough over the end of the cot. Children can move freely in this, and are quite comfortable and free from pain. This device is very much in the experimental stage, however, but promises well.

(iii) Grafting

The envelope system of treatment has been successfully employed in the early preparation of an area for grafting. When a denuded area has progressed under treatment sufficiently to be ready for skin-grafting an irrigation is carried out and the envelope immediately removed. The whole area to be grafted is gently wiped over with gauze soaked in 1% E.S.H. Grafting is then carried out in the usual way. The skin-graft may be kept in position by a sheet of perforated coated silk stitched to the surrounding skin; a new envelope may now be applied, and after twenty-four hours have elapsed irrigation once daily with 1% E.S.H. can be resumed. In many cases the skin can be taken from the same limb and both areas healed in the one envelope. The system is not in any way meant to displace skin-grafting. It is left entirely to the surgeon in charge of the case to decide whether he will leave the area to epithelize or whether he will carry out an early graft. In any case, the use of the envelope will ensure the prevention of secondary infection.

(iv) Wounds and Lacerations

I have confined myself to the treatment of burns, but after watching the results of the treatment of various injuries and septic conditions by other workers have felt that the system will open up a new field of work in connexion with the problem of dealing with septic wounds—in fact, with most septic conditions. Various surgeons are using this method in treating septic fingers and infected tendon sheaths, cellulitis, osteomyelitis, varicose and trophic ulcerations, various types of dermatitis—in fact, all surgical cases in which non-traumatic cleansing, prevention of secondary infection, and early restoration of function are important. While the results from the closed-plaster method are excellent, the very fact that expert surgery and proper hospital accommodation are needed for success in this type of treatment prevents its use in most cases on active service, and it is here that the usefulness of the envelope system will be found.

About two hundred cases have now been treated by this method. Detailed below are five illustrative cases.

Case I

A man aged 64 was admitted on January 14, 1941, with phagedaena of the whole of the flexor surface of the left arm. He had grazed a knuckle two days before, and the arm had become painful and swollen. On examination the whole of the flexor surface of the arm had an appearance of one large sanguineous blister, and a vivid erythema was rapidly spreading over the shoulders and on to the face. The patient looked ill. Saline compresses and sulphapyridine were ordered, but without effect.

strong and supple. Discharged two days afterwards
completely healed. Full movement of limb.

I was asked to see the case in the Radcliffe Infirmary, Oxford, by Mr. Abernethy, to whom I am indebted for permission to publish the record. The patient's arm was washed down for half an hour with 50% solution of E.S.H. and the arm fitted with an envelope. From the time of this irrigation the spread of infection was controlled, and within five days the whole of the skin and subcutaneous tissues had come away in one large slough, leaving the muscles and large blood vessels completely exposed. Daily irrigations of 10% E.S.H. were carried out, and in three weeks the whole of the area was covered with healthy bright red granulation. The patient was very well, was completely comfortable, and had almost free movement of his arm. A Thiersch graft was done on March 11 and the arm irrigated with 1% E.S.H. after twenty-four hours.—This graft took perfectly. Further grafts were carried out. By March 28 all the skin-grafts had taken and the whole area was healed. The man had full function of his arm, and the new skin was quite supple. He was discharged healed with free function on April 7, and when seen on April 29 the skin was found to be very good, with only slight scarring, but complete function.

Case II

A man aged 25, admitted January 13, 1941, suffering from deep second-degree burns of back and side of hand and wrist, due to petrol on sleeve catching alight. Total area, 105 sq. cm. He was not shocked or in obvious pain, but there was some oedema and stiffness. He had had no previous treatment.

Morphine 1/4 grain was given, and in the theatre the hand was immersed in 12 pints of 10% E.S.H. at 100° F. and washed down for twenty minutes. All loose skin was cut away to periphery of burn. Patient experienced no pain, merely describing sensation as "tingling." A full-arm envelope was then applied. Next day the patient was completely comfortable, and slept well without a sedative. All oedema had disappeared, and a shiny film covered the wound. Thrice-daily irrigations were carried out with 8% E.S.H., and there was extensive epithelization, especially at the wrist. On January 21 a slight irritation was observed at the wrist, and oil was added after the irrigations. On the 26th the hand was cleansed and a new envelope fitted owing to the clouding effect of the oil. All sign of irritation was removed on giving ascorbic acid, 50 mg. thrice daily. By February 9 epithelization was complete, and the hand had perfect function.

At no time had the patient experienced any pain. There was no dermatitis under the seal, and the slight irritation in one part of the arm disappeared on administering 50 mg. of ascorbic acid t.i.d.s.

Case III

A woman aged 42 discovered in 1938 that she had diabetes. She went into hospital in London and was stabilized on a low starch diet, without insulin. Her urine was free of sugar for two days before she was discharged, but it had never been tested since. Diet worked until evacuation 6 weeks previously, when she began to eat starchy foods occasionally. Her condition became worse, so under protest she came into hospital. During the day her right leg had been badly burned by a hot-water bottle.

She was admitted on March 11, 1941, in semi-coma and was given 50 units insulin subcutaneously and 50 grammes glucose, also 2 pints of water by mouth. The following day she appeared fit and sat up in bed; felt better; given 15 grammes glucose intravenously. Blister burns from hot-water bottle on back of thigh burst, and were dressed with tannafax. On the 21st the burn was in very bad state, and sloughs were forming.

Operation, March 22.—Area of burn from flexor surface of knee extending upwards seven inches; two inches across top and five inches across at knee. The whole skin sloughed away under irrigation with 10 pints 10% E.S.H. at 100° F., and the area began to bleed. There was suppuration into the fat. Edges of wound were ragged. By the time the envelope was fitted haemorrhage had ceased.

Two swabs were taken of burn before irrigation, with the following results. 1 (a), Gram film: numerous pus cells, few Gram-positive cocci. (b), Culture: haemolytic streptococci, *Staph. aureus*, diptheroids. 2 (a), Gram film: few pus cells, few Gram-positive cocci. (b), Culture: haemolytic streptococci, *Staph. aureus*, diptheroids. The burned area filled with granulations in seven days, and was completely epithelized in three weeks. The patient was discharged healed, with good skin, on April 30. When seen on May 7 the skin was becoming pinker, and was quite supple and fine. She states that at no time did she experience any pain from the irrigations or any discomfort, either day or night.

Case IV

A man aged 26, admitted January 29, 1941, with petrol burn of palmar surface of wrist and hand, and two small areas on each side of dorsal surface of hand—second degree. Morphine 1/4 grain was given intravenously, and the hand was washed down for twenty minutes with 20% E.S.H., finishing with 10%, for eight minutes. All blistered skin was excised. Patient did not complain of any pain, merely remarking that it was "tingling." After five minutes of washing the capillaries dilated and soon burst, but the slight haemorrhage persisted for only five minutes. The whole area became covered with a shiny fibrinous film. A hand envelope was fitted, and was inflated with oxygen.

The next day two washings with 5% E.S.H. were carried out, and the patient was discharged for daily treatment as an out-patient. The hand was irrigated with 5% E.S.H. each day, and epithelization was rapid. On February 10 the envelope was removed, and all areas were found to be covered with a pink cuticle. The hand was quite painless to touch and full movement was possible. The patient was discharged to return to work in a few days. He reported on February 20 having been employed as a bricklayer for a week. The epithelium had cornified owing to the hard work, and local and general conditions were excellent.

This case shows that the method may be used successfully in the out-patient department.

Case V

On January 27, 1941 the patient, a woman aged 25 was cleaning the grate and turned round to tie up one of her children's shoe-laces, when the back of her dress caught fire. She unsuccessfully tried to tear off the dress, thus burning her hands, and then plunged herself into a bath which happened to be full of water. The vicar's wife applied dressings of bicarbonate of soda, and the doctor was called in. At 1 p.m. she was brought into the Radcliffe Infirmary.

Examination showed extensive burns of the second degree from scapulae to scrum, involving the right buttock; and of both hands, of second and third degree, extending over wrist and lower right forearm. At 1.10 p.m. morphine 1/4 grain was given, and at 2.50 p.m., in the theatre, the burns were irrigated with 10% E.S.H., all blisters and dead skin being removed. The left hand was immersed in 10% E.S.H., and some of the blisters were opened. The patient was encased in a coated silk envelope and the left hand in a hand envelope. She was returned to the ward and placed in a hot-box. At 7 p.m. the right hand was immersed in 10% E.S.H. and at 8.15 p.m. an envelope was applied.

The patient passed a comparatively good night, and next morning cleansing of the hands was attempted in the ward, but the burns proved to be too extensive. At 4.55 p.m. on the 28th blisters were removed in the theatre under gas-and-oxygen. Burns of the palmar surface were partially third degree. Hands were soaked in 10% E.S.H., and the envelopes reapplied. At 8 p.m. 1/3 grain of omnopon was given.

January 29.—Tolerable night. All three envelopes were irrigated with 5% E.S.H. and dried with oxygen.

January 30.—In theatre envelopes were removed. Back was washed with 5% E.S.H., and a new envelope enclosing the trunk and arms was applied. Movement of hands quite good.

January 31.—Envelope irrigated twice with 5% E.S.H. Sulphapyridine given.

February 1.—Patient not so well to-day. Complained of "stinging" on back. Arms irrigated 5% E.S.H. t.i.d. (An experiment was being carried out to determine whether the healing in the envelope method is due to the mere fact of isolating the part from secondary infection and from any irritation, or whether the E.S.H. is associated with the envelope in healing.) Patient's hands are being irrigated in the normal manner thrice daily, but the back is left untouched.

February 3.—Hands and arms irrigated with 5% E.S.H. t.i.d. Movement free.

February 7.—Hands and arms irrigated with 5% E.S.H. t.i.d. Back is covered with thick yellow exudate, which gives off a fetid odour. Where the exudate has run away from the burnt area healing has proceeded rapidly, but where the exudate has collected in the small of the back the granulations are unhealthy and healing is delayed. In the theatre the back was washed with 10% E.S.H. and all exudate removed. The whole was covered with a coated silk sheet.

February 8.—Back much cleaner, but still slightly painful when irrigated with 5%.

February 11.—Back is epithelizing well. Right hand has been removed from the envelope, and has perfect function.

February 13.—Bath given in coated silk. Right hand now quite well.

February 17.—Patient walked to bathroom and lay in E.S.H. bath for twenty-five minutes. Her back is almost healed, and feels "wonderfully comfortable." She is able to lie on the area, and moves quite freely.

February 18.—Patient walked to bathroom for her E.S.H. bath. Both hands are completely healed and have perfect function. There is no pain at all. The back has one small area on the lumbar region which has not healed over.

February 20.—Washings in bathroom are continued. Patient is happy and contented. There is still a small area on the back not healed.

February 28.—Patient discharged with hands perfectly healed, but one small area on the back not yet epithelized. She was given some E.S.H., with instructions how to use it on this small patch.

April 8.—Patient seen as out-patient. She uses her hands for heavy household duties, including the washing of clothes. The new skin on her hands is not shiny or tense, as in the case of treatment under tan, but is supple and allows free movement of all parts of the limb. There are no signs of scarring. Her back is quite healed, but the areas which were slowest in epithelizing are slightly raised. She can bend down and touch her toes quite easily, and is very well.

Clinical Progress

The preliminary irrigation rapidly cleans the whole area of the burn or wound. In many cases there is considerable capillary dilatation and transudation with spontaneous haemorrhage, which stops very quickly with the production of a shining fibrin coagulum; the patient feels little or no pain during the irrigation, and is almost always comfortable afterwards. Soreness may persist for a few hours in some cases of secondary burns. Oedema is often visibly reduced during the washing, and the patient may remark on the loosening-up of an affected limb. Excessive exudation tends to cease at the end of the washing. No signs of aggravation of primary shock have been seen. Tissue and bacterial toxæmia are favourably controlled, provided that the burn or wound has been adequately cleansed and all dead material removed. The latter is softened by irrigation, its adequate removal being thereby much eased.

So far as the daily irrigation through the envelope is concerned the patients remain comfortable and can lie on the burnt area with ease. They usually look forward to the irrigation, which they describe as soothing. In most cases temperature and pulse quickly settle and the burn or wound heals rapidly. Movement is encouraged, since it is certain that skin grown on a functioning joint is more likely to withstand use than skin grown on an immobile limb. Patients with burnt hands are made to use them as soon as possible from the time of the application of the envelope. They are encouraged to use a knife and fork and to grasp objects.

The morale of the patients is high and confidence is gained from the start; one never sees the frightened staring appearance so often associated with burns. Some apprehensive patients may describe the irrigation as giving a "tingling" or "pricking" sensation. This is never really unpleasant, and has usually disappeared after the first two irrigations. Secondary burns are more sensitive than primary ones. When epithelization is slow, short-wave therapy may accelerate it.

It has been found that the new skin grown over damaged areas as in third-degree burns is of sound and well-vascularized quality, though perhaps there have not yet been enough cases over a sufficient period of time to form final conclusions on this point.

It has been said before that the primary aim of this treatment is the control of infection. It has never yet been possible to sterilize a wound or the inside of an envelope, but from the clinical signs, and from the fact that the burns heal, it seems that the infection has been adequately controlled. There are some who would even go so far as to say

that a sterile wound is probably not desirable. Be that as it may, normal healing has been obtained in ten days by this method, and yet bacteria could be grown in the envelope. It must be said, however, that the numbers of bacteria are very small, and in some cases growth is difficult.

Results of Treatment Analysed

The following are the results of treatment of specific parts of the body.

Hand Burns.—In six cases treated by me relief of pain was immediate. The patients were encouraged to use their hands as much as possible, with the result that in all cases full function, with complete healing, was obtained within three weeks. Second-degree burns were healed, with full function, in ten days. In those cases in which it has been possible to follow up the results it is noteworthy that the new skin is quite free from scarring and is standing up to hard work. There is no sign of contraction.

Burns involving Joints.—Because full function is encouraged and obtained in every case, the new skin is grown to a fully flexed joint and is therefore not stretched at full flexion. Consequently there has been no breakdown of skin on a joint. In one case in which the joints were opened by the burn the hand was healed and is a satisfactory functioning member.

Face Burns.—In the few cases treated oedema of face and eyelids has been reduced completely within twenty-four hours and healing has progressed without interruption. There has been no sign of scarring or of involvement of the eyes or eyelids.

Body Burns.—Various areas of the body have been successfully treated in a vest, a "perineal bath," or a "full casualty bath."

Burns of the Perineum, Buttocks, and Upper Thigh.—The use of the perineal bath has given complete comfort to the patient and made the dressing very much easier than normally in this region. There has been no ascending infection of the urinary tract, and with the exception of one extremely severe burn of a quarter of the body surface, no infection from the urine or faeces. In the one case infection from pyocyanus occurred, but this was rapidly controlled.

Combined Burns and Fractures.—No case of combined burn and fracture has been treated, but from the experience gained in the treatment of compound fractures by this method it is quite certain that the problem can be solved by applying the necessary splinting outside or inside the envelope, whichever is desired.

Electrical Burns.—Uniformly good results have been obtained in the cases treated, resulting in full function within three weeks.

Chemical Burns.—One case of severe chemical burns has been treated under my direction at a military hospital.

A soldier was accidentally burned by mustard gas on both buttocks, involving the perineum, scrotum, penis, and anus. After ten days I was asked to treat the case. The patient had a thorough washing down with 20% E.S.H., the dead skin was removed, and a perineal bath was fitted. He was irrigated three times daily, and at the end of three weeks was discharged healed, and able to touch his toes without bending his knees.

Dermatitis.—There have been isolated cases of slight irritation of the skin. By changing the envelope and washing it before refitting, by lowering the concentration of the solution, and in one case by the administration of ascorbic acid, the trouble has always cleared up. It is rare to find the slightest irritation beneath the seal.

Chemotherapy.—It would appear that the sulphonamide type of bacteriostatic agent works at its best when dead organic matter is not present. An initial cleansing of the area to be treated with E.S.H. solution enhances the value of these agents. It may be that in a very septic case a

combination of the two types of treatment will be most successful. At present sulphanilamide is being tried out in the envelopes; hypochlorite is used to wash away exudate, and the envelope to prevent secondary infection.

Active Service.—The treating of burns and wounds with an envelope and sodium hypochlorite irrigation was devised as a simple method suitable for use under active service conditions—for example, in field ambulance, dressing station, or in the sick bay of a man-of-war. Its small bulk, its ease of application, and the fact that hypochlorites may be obtained anywhere should make it a most useful addition to modern surgery in warfare.

Conclusions

We feel justified in making claims with some certainty on several points, chief of which are: pain is relieved; primary infection is controlled, secondary infection prevented, and function restored at the earliest possible moment; primary shock is not aggravated, and secondary shock is minimized.

It is a system of treatment which will produce satisfactory results when used in small hospitals without specialist training, in ships, and in fact wherever the simple needs of the system are met. The catastrophes seen heretofore cannot occur when this method is used.

Future developments are in the orthopaedic field, in industrial accidents—in which immediate rehabilitation is so important—and in all branches of war surgery. Numerous varieties of treatment are possible, and many methods which were sound in conception but failed because of secondary infection may now be tried with an envelope, with the assurance that this problem will not arise.

Summary

Investigations into an improved form of dressing for burns and wounds are described.

The reasons for considering electrolytic sodium hypochlorite to be the best antiseptic to use are outlined.

The method of irrigating burns and wounds with this antiseptic, and dressing with coated silk envelopes which do not need daily changing and which shield raw areas from exposure to air and secondary infection, is described.

Burns and wounds covered with coated silk envelopes and irrigated with the appropriate concentration of sodium hypochlorite solution heal rapidly and painlessly, with the maximum preservation of function. The disadvantage of the painful daily changing of dressings is eliminated.

The envelope dressing can be combined with plastering or splinting in cases of fracture, and ulcerations of all kinds may be treated with advantage.

Five of the 200 cases treated by this method are described in detail.

Results are given of the treatment of burns on various parts of the body.

The advantages of this method of dressing for use during active service are emphasized.

I have to acknowledge my gratitude to Surgeon Rear-Admiral Cecil P. G. Wakeley, Mr. Vaughan Hudson, F.R.C.S., Mr. R. V. Hannay, F.R.C.S., Dr. Bruce Pearson, Prof. Hugh Cairns, F.R.C.S., the staff and sisters and nurses of the Radcliffe Infirmary, Oxford, and to all those who have so kindly helped and encouraged me in these investigations. Especially, I have to put on record my appreciation of the way in which Mr. Wm. Stannard has co-operated with me in the development of the envelope system.

M.M. Montgomery and J. D. Kirsbaum (*Arch. intern. Med.*, 1941, 67, 609) illustrate the rarity of anastomotic jejunal ulcer occurring after gastro-jejunostomy alone or combined with gastric resection by the fact that they could find only eight cases among 13,000 consecutive necropsies performed at the Cook County Hospital from 1929 to 1940. All the patients were white men and their average age was 49. Perforation and haemorrhage were frequent causes of death. The interval between operation for the original peptic ulcer and death varied from six weeks to twenty-one years, the average being eleven and four-tenths years.

WOUNDS AND BURNS TREATED BY COATED SILK FABRIC

A REPORT UPON AND CONCLUSIONS DRAWN FROM THE TREATMENT OF 82 CASES

BY

RUPERT VAUGHAN HUDSON, F.R.C.S.

Surgeon to the Middlesex Hospital and to an E.M.S. Hospital

On November 6, 1940, Bunyan and Stannard reported a case in which a large infected burn of the thorax and abdomen in a child was successfully treated in an occlusive envelope by immersion in and irrigations with electrolytic sodium hypochlorite. The envelope was manufactured by Stannard, and the electrolytic sodium hypochlorite was the proprietary preparation "milton" fluid, stabilized to 1% of sodium hypochlorite. The method seemed worthy of trial and capable of extension to wounds. Investigation was started in November, 1940, upon two main lines:

1. The use of coated silk fabric as (a) a fashioned dressing in the form of an envelope, and (b) an unfashioned dressing in the form of sheeting.

2. The clinical uses and properties of (a) electrolytic sodium hypochlorite, and (b) the sulphonamide group in conjunction with this special fabric.

In all, 82 cases were chosen because they showed ulceration in some form or another, or ulceration and infection. In a certain number the method was used because all other treatments had failed to relieve pain or to heal the wound, and one was at a loss to know how to proceed. The patients were treated at the Middlesex Hospital and the E.M.S. hospital to which I am attached. Although improvement in technique is continuing to be effected, it is felt that it is not too early to evaluate the results for the benefit of other general surgeons. In addition, there has been obtained a standard that enables us to contrast the quality of other substances. The following is a classification of the 60 cases whose treatment has been completed, 22 further cases being still under treatment:

1. Burns, primary and secondary.
2. Ulcers and gangrene.
3. Severe lacerating wounds, including compound fractures.
4. Acute pyogenic lesions.

Strict attention was paid to the treatment of shock, the use of prophylactic sulphanilamide compounds, surgical toilet, and constitutional and rehabilitation therapy when indicated.

Method of Treatment

In many cases the application of the envelope or sheeting, and in all cases the treatment, have been conducted by the nurses and dressers, who have also taught some of the patients to treat themselves. The envelopes were used as an occlusive or inoclusive dressing. The occlusive dressing was fixed to the intact skin of the patient by means of the seal incorporated in the envelope and reinforced by a light turn of the strapping; the inoclusive dressing by the removal of the seal, and the maintenance of the position by a light turn of the bandage, enabling the envelope to be removed at will for treatment or sterilization. The occlusive method provides the best means yet devised for minimizing the conduction and conveyance of infection, provided that the wound and the inside of the

envelope are kept clean and dry, using a bactericidal or bacteriostatic agent of non-irritant properties. Sheeting was cut to the required shape and used as a pre- and post-operative dressing, or during the operative procedure. As a dressing it was lightly strapped or fixed with mastisol to the intact skin or laid upon the wound and maintained with a minimum of dressings, care being taken to provide a redundancy of fabric, enabling free drainage and tissue "breathing space." In this way it was found of value in primarily sutured wounds, as a covering for raw tender areas, and as a protection of the skin around colostomies and fistulae. In the theatre it was successfully used for "towelling off" operation sites, to protect abdominal swabs, and for the drainage or light packing of large wound cavities—in fact, it was employed wherever bandages and dressings could justifiably be avoided or minimized, and in

an irrigation room. For a few cases gravity irrigation can be dispensed with and pressure irrigation substituted by means of a Higginson syringe and a tube leading to a suitable container. By these methods the average life of the occlusive envelope was three weeks, and the sheeting lasted many weeks, provided it was washed with soap and water and boiled for the adequate period of two to three minutes only. At the termination of each irrigation the envelope and the wound were dried by postural drainage or suction, oxygen being blown through the envelope to complete the process. The sulphonamide compounds consisted of 20% sulphanilamide or sulphathiazole in a mineral base or as a powder. The employment of these compounds by mouth or parenterally was adopted in all cases in which their use as a prophylactic measure was rendered advisable by the probability of infection. Locally they were introduced in all primarily sutured wounds and applied to certain open wounds. The frequent occurrence of *Staph. aureus* suggested the use of sulphathiazole or a similar compound. Previous work and clinical experience appear to confirm that the efficiency of chemotherapy depends upon free access to normal tissue and to the invading organisms: it does not prevent infection in irregular deep wounds or those containing debris and dead tissue. Its local action is relatively evanescent. A clean wound and frequent reapplication therefore are necessary, and its use was confined to wounds cleansed or kept clean by irrigation. An emulsion or mixture in a mineral base was particularly suitable for the face, where powder imparts a feeling of stiffness and discomfort.

Burns

The total number of cases was 27—primary, 12; secondary, 15. The so-called toxæmia of burns has not occurred; on the contrary, in secondary burns it has been abated.

Primary Burns.—The patient was considered to have a primary burn if he was received within a few hours without having had previous treatment of any duration. Toilet was as gentle as possible, no rough handling or scrubbing being permitted. In certain cases the toilet was by preliminary immersion or irrigation without anaesthesia. Blisters were removed; if they arose subsequently they were dealt with by sterilized scissors through one of the inlets of the envelope. The relief of pain was remarkable, and the average healing time, with full function, was eight to ten days in superficial burns and twenty-one days when focal areas of deeper burns were present. Superficial burns of the face were treated by sulphanilamide or sulphathiazole cream, reapplied morning and evening. If crusts formed they were irrigated away by means of electrolytic sodium hypochlorite before the application of each treatment. A simple face mask was cut from the sheeting and used for the first day or two of the treatment; beyond this the area was left exposed to the air. These results were very satisfactory, pain being slight and cosmesis excellent. The average healing time was six to eight days. Here are two illustrative cases:

Ambulatory Case.—A man aged 38 was admitted on May 11, 1941, with a severe burn of his left hand, which showed large areas of blistering and several areas with complete loss of epithelium. Both dorsal and palmar surfaces were involved, and the burns extended into the web between thumb and index finger and into the webs between the other fingers. The burn was caused when dealing with a burning tarpaulin, the lighted tar from which had dropped on the hand. The blisters were removed and an envelope was applied, irrigations with 5% electrolytic sodium hypochlorite being carried out three times a day. The patient was advised to use his hand, and to put his thumb and fingers through a full range of movement at least once a day. After twenty-four hours he attended as an out-patient for his irrigations. Pain, a prominent feature before irrigations were started, disappeared, and did not return.

FIG. 1

FIG. 3.

place of rubber tissue; thus one easily sterilizable substance acted as an efficient substitute for several kinds of surgical equipment.

The irrigation, its duration and frequency, depended upon the area of the wound and its cleanliness. In clean wounds the minimum number of irrigations was two, morning and evening, and with dirty wounds at least three during the twenty-four hours. The average duration of the irrigation was ten minutes, and the temperature a constant 100° F. The strength of the solution was 5% of the 1% stable electrolytic sodium hypochlorite in tap-water; this strength was reduced to 2½% if the patient showed discomfort or a dermatitis, and as a routine when the wound became clean. The treatment was continued until the wound was healed or ready for primary suture or skin grafting.

In dealing with a number of cases it is essential to provide the nursing staff with suitably large containers, placed at a convenient height on a wagon, or to establish

After five days the burn was practically healed in its entirety, and the patient's only complaint was that a small puncture had been caused in the envelope while he was unloading some heavy barrels from a brewer's dray! On May 20, nine days after the start of the treatment, the envelope was removed, complete healing having taken place in spite of full work, and the final result is a hand whose function is every bit as good as before the accident.

Air-raid Casualty, complicated by Penetrating Wounds.—A woman aged 29 was admitted during the night in an intense air raid, suffering from severe shock. Blood pressure 80/40. She was unable to speak and semi-comatose, was filthy dirty, and had extensive first-degree and second-degree burns of the whole face, neck, and upper part of the chest, the whole of the right arm and hand, the right leg and thigh, and the left leg. In addition there was a foreign body and an open wound in the left arm and left leg. A plasma drip infusion was given, and after the second bottle the blood pressure was improving and the patient's general condition became more satisfactory. Clothing was carefully removed without disturbing the patient, who was nursed on a bed placed on high blocks. An envelope was applied to the right arm, the right leg, and the left leg. These envelopes were slowly filled with a 10% solution of electrolytic sodium hypochlorite by means of a tube attached to a tap tied into the drainage inlet, the remainder of the inlets being tied off. The face was gently cleaned up and covered lightly with sulphanilamide cream. The left arm was covered with a sterile towel. After half an hour's soaking the filthy residual fluid was drained off by means of a tap and rubber tube introduced into the uppermost inlet drainage site. The envelopes were filled once again with a 10% solution. About four hours after admission the patient was fit enough to be transferred to the theatre, where she was given an anaesthetic—nasal gas-and-oxygen—and pentothal into the drip, which was still running. The metallic foreign body was removed from the left arm; the wound in the left thigh was excised and decompressed, there being extensive muscle damage, but the foreign body proved to be inaccessible. The right arm was left in the original envelope. The right leg envelope was changed without cleaning up the leg; but the left envelope had to be removed in order to enable us to excise the wound, and the limb was replaced in a clean envelope. The left arm, after the removal of the foreign body, was cleaned up and then covered with sulphanilamide cream and bandaged with gauze and wool. In the early hours of the next morning oedema of the face was pronounced and the eyes were completely closed. The patient's general condition slowly improved, but it was not until the fourth post-operative day that her mentality was normal. Throughout the whole period she complained of severe and persistent pain over the left side of her thorax, and on one or two occasions coughed up some black sputum. Although the radiographs of her chest were negative, the physical signs and diagnosis pointed to a localized blast area of the lung. The envelopes were irrigated three times a day with 5% electrolytic sodium hypochlorite, and after a light toilet the sulphanilamide cream was changed twice daily, the face and chest being covered by a mask of coated silk; this mask was replaced by a clean sterilized "fellow" at each change of the dressing. About the sixth day she complained of discomfort in the left arm. The bandages and gauze were removed, and it was found that her discomfort was mainly due to the fact that the dressing had become adherent to the multiple sites of the burn. This dressing was replaced by sulphanilamide cream and a coated silk sheeting, lightly bandaged in position, without any gauze and wool. Thereafter she was quite comfortable. It was noteworthy that this arm was swollen and oedematous until the dressing had been changed; but, on the other hand, the oedema of the face had completely resolved by the fourth morning, and at that time there was no oedema of the limbs treated in the envelopes. Throughout the period, movement of the limbs in the envelopes was free and painless, and the patient required only one dose of morphine. The temperature never rose above 99° for the first three days and subsequently was normal. Twenty days after admission all wounds and burns had healed and full function was present. It must be stated that, although the parts injured were very extensive, there were multiple localized areas under the extremities, but the face, neck, and chest consisted of one large superficial burn. With the exception of a few focal points the burns could be described as of first and second degree. As is usual, up to the third and fourth day blisters tended to make their appearance, and were removed, without interfering with the envelopes, through a convenient inlet hole made with sterilized scissors. Two wounds, which necessitated wide surgical exposure down to the bone, healed by primary union. So far the cosmetic appearance is excellent.

Secondary Burns.—Patients admitted some days or weeks after receipt of the burn were regarded as secondary cases,

the burn being complicated by infective ulceration. These were cases in which the use of tannic acid, sulphanilamide and tulle gras, saline dressings and flavine dressings, among other treatments, met with failure. All were heavily infected, usually with the triad *Str. haemolyticus*, *Staph. aureus*, and *B. coli*, and suffered from pain and toxæmia. Either with or without an anaesthetic, according to the condition of the patient, initial treatment with a long irrigation of 5%, increasing to 10%, was used to clean up the wound and remove debris and pus. A suitable envelope was applied and irrigation treatment given. The length of time taken to clean up the wound was a matter of a few days only, and it was interesting to note that during treatment intact islets of epithelium began to appear, as survivals of the original burn and the infective ulceration caused by the previous treatment. The average length of time taken to heal the wound depended on the area and whether grafting was employed or not. The following are two illustrative cases:

A woman aged 20 was treated as an out-patient in a casualty department which had achieved success in minor superficial burns by the use of sulphanilamide cream and tulle gras. She had a large superficial burn complicated by an unsuspected deep burn. Ten days after her injury she was admitted with pyrexia, pain, oedema, and infection originating in the coagulated debris of the deep burn, 4½ in. by 3 in., on the extensor surface of the forearm. A rapid relief of symptoms was obtained by the use of the envelope and irrigations. Healing took place in forty-two days. Skin grafting could have been employed at an earlier date, and would have considerably shortened her convalescence. It should be noted that sulphanilamide did not prevent the area of necrosed tissue from becoming infected.

A man aged 73 was admitted three weeks after a fall into a fire. He was ill, pyrexial, and had a cough and bronchitis. The burnt area extended over half the dorsum of the thorax and the whole of the upper arm, reaching below the elbow-joint. This was covered by a suppurating mass of tannic acid and silver nitrate coagulum, containing *Staph. aureus*, coliform bacilli, and diphtheroid organisms. Suitable sheets of coated silk fabric were used as a dressing and to protect the bed during irrigations. Irrigations were started three times a day with 5% electrolytic sodium hypochlorite. After each irrigation sheets of coated silk fabric were laid over the raw area. The improvement in the general condition and the relief from pain were remarkable. In two days the whole of the coagulum and slough had been irrigated away. Five days after beginning treatment a "vest envelope" was fitted. The patient lay or slept on his back and needed only a ward jacket over the vest when sitting up in bed or in a chair. Gradual healing proceeded; the vest was removed and tulle gras and sulphanilamide dressing were instituted. In five days lysis of a considerable area of new epithelium had occurred. A new vest was fitted, and again epithelization proceeded apace. It is now seventeen weeks since the beginning of treatment, and only two small areas remain to be healed. The age of the patient and the bronchitis precluded saline bath treatment; but the bath, in the shape of a vest, was most successfully brought to the patient, permitting painless treatment and ambulation, and resulting in spontaneous healing of a vast area. Had the patient been younger, skin grafting, done at an earlier stage, would have shortened treatment and obviated a degree of contracture at the elbow-joint and posterior axillary fold.

• Ulcers and Gangrene

The total number of cases was twenty-six. These consisted of 14 varicose ulcers, 5 traumatic ulcers, 2 varicose ulcers and syphilis, 1 chronic infected olecranon bursitis, 1 radio necrotic ulcer, 1 Meleney's ulcer, 2 Burger's disease.

With the exception of the Meleney's ulcer, which was unaffected by treatment, all were benefited. Surprisingly, a tabetic patient with a perforated ulcer of the foot, uncomplicated by an osseous lesion but complicated by cellulitis, was healed in three weeks. The 2 cases of Burger's disease were treated as a preliminary to surgery. The 14 cases of varicose ulcer are worthy of mention. They consisted of patients admitted for ligation and injection

treatment, and formed a group which had had every known method of treatment, the envelope being used as the sole remaining measure. These patients certainly were kept from their work, but particular attention was not paid to resting them in bed. They were allowed to get up and sit or walk in the ward. In those cases in which the bacteriology was investigated the usual organisms were again the triad *Str. haemolyticus*, *Staph. aureus*, and *B. coli*. These ulcers are notorious for their tendency to break down again even after firm healing, and this may occur in our cases; but the rapid freedom from pain and the sound though slow healing of the ulcers made the treatment worth while. The following is a representative case:

A woman aged 88 had for thirteen years suffered severe pain and disability from a varicose ulcer, 1 in. by 1 in., situated immediately above the right external malleolus of the fibula. It was completely resistant to all previous forms of treatment. A fixed talipes equinus deformity was present, due to this ulcer. She was admitted, was fitted with an occlusive envelope, and was given irrigations of 5% electrolytic sodium hypochlorite thrice daily; these were later reduced to 2½% twice daily. In three weeks the ulcer was soundly healed. The train and bus fares to the out-patient department, the dressings, remedies, and medicines had cost her, and hospitals, many pounds a year.

Severe Lacerating Wounds, including Compound Fractures

The total number of cases was 15: 10 severe lacerating wounds, 5 compound fractures.

In primary clean cases with loss of substance the wound after surgical toilet was treated in an occlusive envelope, resulting in return of function and avoidance of infection. In certain cases of mutilating injuries with ingrained oil and dirt, amputation was avoided and some function preserved by this method. In infected compound fractures with loss of substance, deodorization and practical disinfection, with healing and union, were brought about. Where traction was necessary the apparatus was placed either inside or outside the envelope. If traction apparatus is placed within the envelope the pins or wires must be of stainless steel or "staybrite," as the great disadvantage of sodium hypochlorite is the destructive action upon unprotected silk and metals.

A man aged 67 was admitted two months after sustaining a compound fracture of the mid-shaft of tibia and fibula, treated by unpadded plaster casts with light packing of the wound and a Steinmann pin through the os calcis. The patient was ill and pyrexial, the plaster dripping pus containing *Str. haemolyticus*—a menace to other patients and medical personnel. The odour was indescribable. Under light anaesthesia the plaster was removed and cultures taken, revealing haemolytic streptococci. The leg was flail at the fracture and up to the knee-joint it was covered with superficial ulcers and pus, the ivory-white dead ends of the tibia protruded through a large ventral ulcer, and posteriorly a large ulcer led to the fibular fragment. The whole area was irrigated for twenty minutes with 10% electrolytic sodium hypochlorite, a sleeve envelope fitted with a ventral opening for irrigation and a dorsal for drainage, and the patient put up in a Hodgen splint. The odour disappeared immediately; comfort was established and treatment was rendered easy. Three times daily the wound was irrigated. The posterior ulcer healed quickly, and the ventral ulcer healed save for an area of one square centimetre where a portion of the tibia is sequestering. The extension has been removed as union is starting, and is firm enough to permit a light Cramer wire padded splint, enabling the patient to sit in a chair. It is now eleven weeks since treatment was begun.

Acute Pyogenic Lesions

The total number of cases was 14: 8 were infections of the hand, 2 cellulitis of limbs, 2 bursitis, and 2 Brodie's abscess of bone.

The cure of suppuration of the hands and fingers, the legs and feet, has long been a matter of difficulty; consequently we made a trial of the envelope method in the

treatment of this condition. The results were determined entirely according to whether free drainage had been instituted and every pocket opened up at the time of the surgical procedure. Provided this had been done, the results were good—better than those of the old-fashioned saline baths or fomentations, as maceration and oedema did not occur. If the drainage provided was not adequate the slight drying action of the electrolytic sodium hypochlorite tended to heal and close the superficial edge of the wound, enabling pockets of pus to collect, necessitating further drainage. Careful watch must be maintained to ensure free drainage and adequate irrigation or immersion, the envelope being removed if pain and oedema are not abating and the area thoroughly examined.

A man aged 31 was admitted six days after a small cut with a knife. There was a suppurative tenosynovitis of the middle finger of the left hand and lumbrical spaces. Under anaesthesia surgical drainage was instituted. The organism cultured was *Str. haemolyticus*. An envelope was fitted in the theatre, and irrigations were given thrice daily with 5% electrolytic sodium hypochlorite. Fourteen days later a small residual abscess in a lumbrical space was opened; healing and return of function proceeded. The wound had healed five weeks after operation, but function is limited, though improving.

In the acute stages of infection chemotherapy was not neglected and the greatest care was exercised in starting movement. Movements that the patient could voluntarily perform were permitted, but only when drainage was perfect and the signs and symptoms of acute infection had subsided. Too early an attempt at rehabilitation may lead to disastrous invasion of organisms, locally and into the blood stream.

Pain

Irrigation can be made painful if exposed nerve endings are traumatized by the force of the stream. The wound must be watched, and the fluid should be allowed to run over a sensitive area and not directed upon sensitive focal points. The abolition of pain is the function of medicine and the patient's criterion of successful treatment. The relief of pain from the use of this method has been remarkable, and has helped in the reconstitution and rehabilitation of the patient.

A woman aged 29 was suffering from a residual deep burn of a large area over the left ankle-joint of two months' duration, with persistent infection due to a combination of tannic acid and plaster treatment. All methods, including saline, tulle gras, and chemotherapy, had failed. Persistent pain necessitated sedatives. Spasm of the whole limb-girdle was present, with consequent slight movement of the hip-joint, less at the knee-joint, and absence at the ankle-joint. An envelope was applied eight weeks after the injury and irrigations with electrolytic sodium hypochlorite begun. After forty-eight hours spasm of the limb-girdle had disappeared. No sedatives were required. In eight weeks the area was healed, with full function of the ankle-joint. During treatment the patient became ambulatory, regularly visiting the cinema wearing the envelope.

Function and Rehabilitation.

The importance of early rehabilitation of the patient cannot be over-emphasized. Below are three cases which illustrate this point.

Ten days after a resection of bone for a chronic staphylococcal Brodie's abscess of the upper end of the humerus in a youth aged 17, the vaselined pack was irrigated away with 10% electrolytic sodium hypochlorite under evipan anaesthesia and an envelope was fitted to the shoulder-girdle. The patient was permitted full movement, and to be up fully dressed, wearing his clothes over the envelope. He shopped and visited the cinema in his usual attire.

A man aged 55 had severe pain due to an irregular varicose ulcer situated over the external malleolus of the left foot; this was resistant to all forms of out-patient treatment over a period of six years. He was unwilling to come into hospital, but lived near enough to undergo ambulatory treatment. An envelope was applied, and he voluntarily attended the irrigation room three times daily as an out-patient, and continued to do

so because, twenty-four hours after the first treatment, his pain had been relieved. He was taught by the nursing staff to administer his own treatment, and attended until, in sixteen days, the ulcer was completely healed.

A woman aged 41 sustained a severe penetrating wound of the left leg from a bomb splinter. The injury involved all compartments of the mid-lower leg, ruptured the anterior tibial artery and interosseous membrane, and caused extensive loss of tissue. The dead and dying tissue was removed and the area extensively decompressed, powdered with sulphanilamide, and packed lightly with vaselined gauze. The limb was then placed in a padded plaster stretching from the toes to the groin. In three weeks, under light anaesthesia, the plaster was removed and the packing irrigated from the gaping wound with 10% electrolytic sodium hypochlorite. The limb was placed in an envelope and irrigations were continued three times a day. Voluntary movements were gradually encouraged and the patient eventually became ambulant. The wound healed in six weeks, with full function of the limb.

Conclusions

The coated silk fabric is a valuable addition to the armamentarium of the surgeon. Its value as a dressing, whether by the occlusive or the unocclusive method, has been proved. Sodium hypochlorite prepared by electrolysis and stabilized has been of pronounced value in this treatment, enabling wounds to be kept clean and dirty wounds to be made clean, with the relief of pain and oedema, and early rehabilitation. As an adjunct to this treatment, the sulphonamide group has been of great service in oral, parenteral, and local therapy. The common factor in successful treatment depends upon the adoption of general surgical principles—the prevention and control of infection, the removal of dead tissue, and the provision of free drainage with the minimum disturbance of tissue. Provided that cases are wisely chosen, rehabilitation and healing can occur simultaneously in clean open wounds in spite of the employment of full movement. The illustrative cases suggest that a full trial should be made of the coated silk fabric under Service, civilian, and factory conditions—as a first-aid measure and as a method of treatment in burns and wounds of minor and major degree.

First Aid.—In extensive injuries the application of a full-length envelope will conserve body heat and lessen shock. A full-length envelope, a local envelope, or sheeting will provide a light, transparent, non-frictional dressing which will diminish pain, permit free drainage, and facilitate inspection and handling without disturbance of the wounds. In first-aid stations or casualty posts remote from a surgical centre, and at the surgical centre during the waiting and resuscitation period, immediate general and local control of infection can be carried out. In the absence of electrolytic sodium hypochlorite, powdering the wound with sulphathiazole may be advocated. During this waiting period before and during transit anti-shock measures should be continued and the blankets and clothing occasionally lifted for the rapid examination of the wound. If oozing is troublesome a firm bandage may be applied outside the envelope to obtain pressure on the wound. Where there is considerable delay in transport, or at the surgical centre, immersion or irrigation therapy may be employed, and be combined with chemotherapy. In the absence of these facilities the repowdering of the wound every twelve hours is suggested. Casualties so dressed on arrival at the surgical centre can be inspected and treated with the minimum disturbance. In gas-contaminated wounded lavage will be facilitated, and with sodium hypochlorite available a direct action upon mustard gas can be obtained. In the wards a ready detection of the earliest appearance of delayed burns will be rendered more certain.

At the Surgical Centre.—The selection of cases regarded as suitable for treatment by these methods may be considered under the headings of primary and secondary methods.

Primary Method: 1. By Irrigation:

(A) Burns whose depth is in doubt, or surgical toilet perforce imperfect. Deep burns unsuitable for primary excision. Burns complicated by penetrating wounds.

(B) Open clean wounds after adequate surgical toilet. Mutilating wounds in which precise surgical toilet is prevented by the ingrainings of oil or dirt. Compound fractures with loss of substance, or in which delay in arrival renders primary suture unwise—provided that skeletal or skin traction, or splinting, can efficiently control the fracture.

(C) The burns, wounds, and compound fractures of the gas-contaminated.

2. By 20% sulphathiazole emulsion or cream:

In superficial burns of the face and as a cream or powder for superficial wounds or burns elsewhere. The surface to be kept clean, soft, and exposed, but the dressings performed daily.

Secondary Method: 1. By Irrigation.

(A) Secondly infected burns. Delayed mustard gas burns.

(B) Wounds in which immobilization by plaster had been necessary, but in which the lapse of time has enabled the acute symptoms to subside and made the establishment of movement safe.

(C) Secondly infected primarily sutured wounds, including compound fractures, as a complement to adequate surgical drainage.

(D) Certain cases of acute infection involving soft, bursal, or synovial tissues.

(E) Chronic, traumatic, infective, or varicose ulceration resistant to treatment by other methods, or as a complement to recognized surgical procedure.

2. By sulphathiazole powder or cream.—To clean healing wounds as a final dressing.

Points that Must be Emphasized:

Movement is only to be encouraged when the wound is clean and acute symptoms are absent.

Free ventilation and redundancy of fabric in the neighbourhood of the wound are essential. Close apposition and superimposed dressings or excess of clothing are to be avoided. The only exception is the deliberate intention of keeping the wound warm and moist.

Strict attention must be paid to the avoidance of conduction and conveyance of infection. Inefficient surgical nursing ritual is the cause of the contaminant organisms arising in the wound and envelope during treatment.

A bactericidal or bacteriostatic agent must be applied, and frequently reapplied, to prevent gross infection and reduce the bacterial count. Without antiseptic methods the coated silk fabric may conceivably encourage growth of organisms.

Catgut (not silk), stainless steel, and "staybrite" (not unprotected metals, should be used when sodium hypochlorite is the irrigation fluid.

The method increases the possibility of the early replacement of skin loss by skin grafting, and this grafting should not be unduly delayed and should be accompanied by sulphonamide therapy.

The average strength of the irrigation fluids used is 5% or 2½% of a 1% stable sodium hypochlorite. Hospitals, ships, and factories having their own plant for the electrolysis of brine should check the percentage of sodium hypochlorite obtained and carefully adjust the percentage dilution of irrigation fluid before use, in order to avoid too strong or too weak a solution.

The treatment needs care and thought. It is not a competitor or a universal panacea, but it has a definite place in surgical treatment.

The average life of the envelope in use is three weeks and of the sheeting used as a dressing many weeks. A considerable economy in bandages and dressings can be effected. Patients have not been averse to seeing their own wounds, but, on the contrary, have been interested and encouraged by their progress. The visibility of the wound has enabled the medical staff and nurses to observe the pathology and physiology of living tissue.

Summary

Twenty-seven cases of burns and 55 of wounds have been successfully dressed with a coated silk fabric, in conjunction with treatment by sodium hypochlorite, prepared electrolytically and stabilized, and the sulphonamide group of chemothera-

peutic agents: twenty-two of them are nearing the end of their treatment. The methods employed and illustrative cases are recorded. The tabulated conclusions provide a basis for an extended trial of these methods as a first-aid measure in the prevention of shock and the control of infection and as a method of treatment in selected cases. The possibility of replacing dressings and rubber tissue by one portable and easily sterilizable substance is suggested. Stress is laid on the necessity and facility for early painless rehabilitation of the wounded.

My most grateful thanks are due to Mr. Rodney Smith, Mr. H. M. Darlow, and many members of the nursing staff and students of the Middlesex Hospital; to the Board of the Middlesex Hospital for facilities afforded to me and my two commandants, Mr. B. W. Windeyer and Dr. Breeze; to Lieut.-Commander Bunyan, Mr. Bruce Pearson, and Mr. Hannay, for their association and help and for allowing me to see their cases; to Dr. Maurice and Dr. Chiesman for their co-operation; to Prof. McIntosh and Dr. Britton of the Bland-Sutton Institute of Pathology, Middlesex Hospital; to Mr. Stannard for his advice and generosity in the supply of envelopes for these research purposes; to the Milton Proprietary, Ltd.; and to Messrs. May and Baker for their supply of materials.

THE VALUE OF THE NON-SPECIFIC FACTOR IN EXPERIMENTAL IMMUNIZATION WITH INFLUENZA VIRUS

BY

J. UNGAR, M.D.

AND

R. F. HUNWICKE, B.Sc., F.I.C.

From the Bacteriological Laboratories, Glaxo Laboratories Ltd.

Influenza is one of the few virus diseases which do not induce in the patient after recovery any manifest immunity, although during and after convalescence virucidal antibodies can be detected in the serum. After a few months have elapsed a second attack may be experienced. As there is only a transitory immunity after recovery from the illness, the possibility of acquiring more prolonged immunity by artificial immunization is very limited.

So far laboratory experiments on ferrets and mice show that it is possible to immunize these animals for a period of about three months only if the virus is applied intranasally. If at the end of that time the virus is injected subcutaneously, immunity can be prolonged over a further period, as shown by the resistance of the ferrets to reinfection by the nasal route (Laidlaw and others, 1935). The only positive effect in the immunization of ferrets and mice by routes other than nasal is an increased resistance in the immunized animals to lung lesions caused by the subsequent application of influenza virus; this may be due to the presence of protective antibodies induced by the previous injection of the virus.

In the blood of immunized animals and in human beings after recovery there can be demonstrated virucidal, precipitating, and complement-fixing antibodies (Magill and Francis, 1938; Hare, 1939; Fairbrother and Martin, 1939; Eaton and Beck, 1940), but their immunizing effect, as demonstrated by insufficient subsequent protection against reinfection, is disappointing in most cases. One possible explanation of this inadequacy is the fact that there are several types of influenza virus; but, on the other hand, these are antigenically very close, as they give a cross-complement-fixation with each other.

Unfavourable reports on the immunization of human beings with the vaccines at present available have been published in this country and in the U.S.A. (Dochez, Mills, and Kneeland, 1938; Powell, Sparks, and Clowes, 1940; Stuart-Harris, Smith, and Andrewes, 1940; and others). The

new combined influenza and distemper virus vaccine introduced by Horsfall and Lennette (1940a, 1940b) seems to be promising, but results are not yet available.

As the usual influenza virus suspensions do not give satisfactory (that is, only transitory) results when applied by routes other than the nasal, we tried to increase specific immunity by adding to the specific stimulus an unspecific factor which would activate the reticulo-endothelial system, or act by simultaneous local irritation of the tissues. This method is often successfully applied in immunization against bacteria and their toxins, and therefore a trial in the case of the influenza virus was logical.

The following experiments were carried out:

Experiment 1

Groups of 50 mice from one stock were given subcutaneous injections of 0.25 c.cm., 0.25 c.cm., and 0.5 c.cm. at weekly intervals of the following three preparations:

(a) A vaccine containing per c.cm.:		
B. pneumoniae (Friedländer)	25 millions	
M. catarrhalis	25 "	
Pneumococcus	150 "	
Streptococcus	150 "	
Staphylococcus	100 "	
C. coryzae	25 "	
H. influenzae	100 "	
Preservative, 0.5% phenol		

(b) A vaccine containing per c.cm.:		
Sarcina	3 millions	
B. mycoides	2 "	
Pneumococcus	1 million	
Streptococcus	1 "	
Mixed lipoids (cod-liver oil, 0.02 mg.; cholesterol, 0.67 mg.; lecithin, 0.1 mg.)	0.187 mg.	
Preservative, 0.5% phenol		

(c) Saline containing 0.5% phenol

Three weeks after the last injection the mice received 0.05 c.cm. of a suspension of influenza virus Type A prepared as follows:

Lungs were removed from mice which had been infected with the virus five days earlier. The lungs were weighed moist, pulped in a mortar, and taken up in broth in the proportion of 2.25 grammes to 10 c.cm. This suspension was centrifuged and filtered through a small Berkefeld candle. The filtrate showed high activity of the virus, as mice were killed by intranasal instillation of dilutions of 1 in 1,000. The injections were made intranasally under chloroform-ether anaesthesia. Ten normal mice were similarly injected at the same time to serve as additional controls.

The results from the three preparations were: (a) 6% survivals, (b) 12%, (c) 11%. Survivals from the controls amounted to 20%.

Experiment 2

A suspension of influenza virus prepared as described above, except that saline was used instead of broth, was incorporated in the following preparations:

(d) A mixture of preparation (a), 2 parts; mixed lipoids as in (b), 1 part; influenza virus, 1 part	
(e) Mixed lipoids, 3 parts; influenza virus, 1 part	
(f) Colloidal calcium, 3 parts; influenza virus, 1 part	
(g) Saline, 3 parts; influenza virus, 1 part	

0.1% formalin was added to all the mixtures, and they were kept in the refrigerator pending animal experiments.

Groups of 24 mice were given subcutaneous injections of 0.25 c.cm., 0.25 c.cm., and 0.5 c.cm. at weekly intervals. One week after the third injection they received 0.05 c.cm. of a suspension of influenza virus intranasally under chloroform-ether anaesthesia.

The results from the four preparations were: (d) 57% survivals, (e) 96%, (f) 79%, (g) 88%.

Conclusions

From the above experiments it is evident that the immunization of mice against bacteria associated with cold infection has no protective effect against subsequent infection with influenza virus. Mice immunized either with a cold vaccine or with a polyvalent antigen show the same

percentage of deaths as the mice injected with phenolized saline.

Having excluded the possibility of the production of non-specific immunity by bacteria, we found in the second experiment that there was no substantial difference between the resistance of animals in the four groups to subsequent infection with influenza virus.

These experiments indicate that the simultaneous application of heterogeneous substances had no influence on the production of immunity against influenza virus.

THE CONTROL OF GASTRIC HYPERACIDITY IN PEPTIC ULCER

BY

WILLIAM E. SMITH, M.A., M.B., Ch.B.

Captain, R.A.M.C.; Carnegie Research Scholar in Medicine

(From the Gardiner Institute of Medicine, University of Glasgow)

In spite of all attempts to discover the aetiology of chronic peptic ulcer it must be admitted that the essential cause still eludes us. Analysis of the gastric juice frequently shows a high acidity, less commonly a moderate or low one, but a total absence of hydrochloric acid is quite unknown in this condition. While we have often concluded that hyperacidity is a cause of gastric ulcer, we have no evidence in favour of this at all. There is more evidence that the presence of HCl tends to continue the activity of an ulcer, once it has formed, and that healing is prevented. For this reason, chiefly, our main attempts at therapy in peptic ulcer have hitherto centred on the continuous neutralization of HCl by diet, drugs, and other methods. Quite probably the acid factor is not the sole cause of an ulcer's not healing, but at present the neutralization of HCl is our main therapeutic weapon. Furthermore, it is already clear that ulcers do heal even when HCl is present in the stomach during part of each day.

Diet as a means of neutralization of acid takes first place, and is given at hourly or at most two-hourly intervals; but it is already known that this cannot bring about continuous neutralization, and, moreover, during the hours of sleep feeding is impossible. Numerous drugs (alkalis and others) have therefore been used, but they are in many ways unsatisfactory. We want to find, if possible, foods or simple drugs that will ensure continuous neutralization throughout the twenty-four hours, or will keep the secretion of HCl permanently as low as possible.

The series of experiments now to be described were undertaken with a view to discovering the most suitable foods or simple drugs to maintain neutralization for as long as possible during the twenty-four hours. The substances under investigation were given two-hourly, and the stomach contents in all cases were examined repeatedly during a continuous period of twelve hours, the Ryle tube

being kept in position; samples were removed for hourly examination shortly before and one hour after feeds. All patients included in this investigation presented clinical and radiological evidence of peptic ulcer, and fractional test meals were first given in the usual way, with oatmeal gruel as the stimulant of gastric juice. Every test showed hyperacidity, and the curves obtained over two and a half hours were in general similar to those described by Ryle (1921).

Methods of Titration

The amounts of fasting juice and residue were measured and all specimens were titrated for free and total acidity with decinormal sodium hydroxide, using methyl orange and phenolphthalein as indicators respectively. Results are expressed as units in terms of c.cm. N/10 NaOH required to neutralize 100 c.cm. of fluid. Only the free-acid readings are here recorded.

Group I (9 Cases)

For purposes of comparison feeds of milk, 10 oz by mouth, were used in each case before other treatment. Parallel experiments with whole milk and citrated milk indicated no appreciable difference between the two in the resultant acid level, and as the thick clots of whole milk were found to block the tube the work was continued with citrated milk, to which alone results refer. Considering the great importance attached to milk in the treatment of peptic ulcer, one would expect to find that it caused a substantial reduction of acidity. But Nicol (1939) could not demonstrate this either by two-hourly or by hourly feeds; indeed, he recorded a higher acidity with milk two-hourly than with a diet consisting of three full meals. Ry quarter-hour readings he showed that a fall occurred immediately following each feed, but only of short duration; before the next feeding-time the level had risen to its previous height. The results of the present experiments are in complete agreement with those of Nicol. Surprisingly high levels were obtained: it was common to find figures of total acidity of 70 to 80 units, and few were below 30. The charts, with hourly readings, did not show the fluctuations indicated by Nicol, but the reference is the same—namely, that milk given at two-hourly intervals has little if any continuous antacid value.

Gelatin (feeds of 10 oz.) was next used, prepared according to the method of La Due (1939)—gelatin 1 part, lactose 3, water 5.2 parts. Andresen (1927, 1939) used this mixture with success in the treatment of haematemesis. I had already tried it as a secretory stimulus in the fractional test meals of 7 patients and had compared the results with those of gruel meals in the same cases. Apart from the fact that gelatin specimens were homogeneous and easier to titrate, no significant differences were noted in the acid curves; similarly, in the twelve-hour tests gelatin appeared to have approximately the same neutralizing power as milk, although the former is supposed to be a powerful stimulant of gastric juice.

The rational use of olive oil in the treatment of peptic ulcer is demonstrated in this series; both olive oil and peach-kernel oil were found to cause a substantial reduction of acidity, an effect already reported by Roberts (1931). In 4 cases three feeds of milk (10 oz.) were given two-hourly followed by three of oil (2 oz.) two-hourly; and in the second half of each test there occurred a fall of 20 to 60 units. The experiments were repeated several times in the reverse order, and a similar depression with oil was followed by a rise to over 40 units under the influence of milk. Chart I represents such curves, obtained from one patient. Peach-kernel oil and an emulsion of olive oil, as will be observed from Table I, are not quite so effective as undiluted olive oil. A criticism was offered that the low acid values were due to the nauseating taste of oil; but this was disproved by the fact that when oil was syringed down the Ryle tube the values were even lower than when it was given orally.

As a deliberate contrast tests were made with two substances which are supposed to be strongly acid-producing—bovril and strained meat stock. The latter has always been excluded from the dietary regimes of dyspeptic patients; but as Table I shows, from the point of view of acidity this is an

unnecessary restriction, as the acid levels were in no case higher than those resulting from milk.

Table I indicates the average readings of the experiments in this group. It would appear that so far as two-hourly feedings are concerned the actual food given is of no account: milk, as a supposedly acid-lowering food, and meat soup, as acid-raising, are shown to be of little value in either respect. Olive oil, however, is a remarkable exception, being a real depressant of acid secretion, and further experiments were designed to estimate its effect in conjunction with milk.

CHART I.—Hourly free acidity of gastric contents over 12-hour periods in one case, with 2-hourly feeds of (a) milk 10 oz. and olive oil 2 oz., and (b) olive oil 2 oz. and milk 10 oz.

Results are expressed as units in terms of c.cm. decinormal NaOH required to neutralize 100 c.cm. of fluid. G.U. = Gastric ulcer. D.U. = Duodenal ulcer. J.U. = Jejunal ulcer. F.T.M. max. = Maximum reading of fractional test meal.

Group II

Confirmation of the acid-depressing power of oil was demonstrated by this series, in which six feeds were given two-hourly by mouth, and 1 oz. of olive oil was syringed down the aspirating tube half an hour before each of the last three feeds. Reference to Table II will show that of the 9

patients examined by this method 4 showed no significant difference between the two halves of the test; in the other 5 the addition of olive oil induced a reduction of acidity of 20 to 40 units. Peach-kernel oil in one case resulted in a depressant effect similar to that of olive oil. The preliminary fractional test meals of all 9 cases gave similar curves (Chart II), and no reason could be discovered for the apparent absence in the 4 case, of a depression by the vegetable oils, an effect which when present in the other 5 was considerable.

CHART II.—Hourly free acidity of gastric contents over 12 hours in one case, with six 2-hourly feeds of milk 10 oz. and olive oil 1 oz. half an hour before the last three.

Group III

The preceding data refer to results obtained with methods of treatment of a purely experimental nature, and it was felt desirable to attempt to evaluate the changes in acidity brought about by methods more applicable to routine treatment. Three patients admitted for peptic ulcer complicated by haematemesis were the subjects of this investigation, and three parallel experiments were performed: (1) Meulengracht - Witts dietary regime alone (Meulengracht, 1935; Witts, 1937); (2) that diet plus olive oil; (3) that diet plus olive oil and alkali.

The procedure was as follows: (1) On the first day gastric specimens on diet alone were analysed hourly; (2) on the second day the experiment was repeated with the addition of 1/2 oz. of olive oil half an hour before meals; (3) on the third day oil was given before meals and 1 drachm of an alkaline mixture (equal parts of mag. carb. pond., bismuth. carb., sod. bicarb.) after meals. The results are summarized in Table III. With the diet alone readings are fairly high; in

the series they varied from 30 to 80 units, and a fall of 10 to 20 units followed each feed. The use of oil depressed the acid level considerably, although in no case did it entirely obliterate free acid. With oil and alkali the reduction was more pronounced, several specimens being neutral in reaction; maximal values, however, were still high.

These experiments show that a dietary scheme which was designed to promote healing of an ulcer does nothing to lower acidity. Olive oil, as in the previous groups, plays its part in reducing acid levels, and a still greater fall is obtained by a combination of oil and alkali.

Group IV

The continuous intragastric drip apparatus has recently been much used experimentally to obtain a constant reduction of acidity. The substances in most common use have been milk (Winkelstein, 1933; Nicol, 1939) and aluminium hydroxide (Woldman, 1937; Woldman and Rowland, 1936; Woldman and Polan, 1939; Browne and McHardy, 1939; Eads, 1940). In the present series other simple foods and drugs have also been investigated. All 7 patients of this group received a standard "ulcer diet" consisting of three meals of easily digested food, not necessarily fluid, and three intermediate feeds, mainly of biscuits and milk. The acid levels with this diet alone were

similar to those in patients treated by the Meulengracht - Witts regime, described above, although the ulcer diet was fuller and more solid: it was thus again demonstrated that such dietary schemes are in themselves of little value in the control of hyperchlorhydria. The substances used flowed at the rate of 10 to 15 drops a minute into the stomach, through either a pharyngeal or a nasal tube with the tip at the cardia, from a container hung above the bed. At hourly intervals the tube was disconnected and swallowed further until the tip was near the pylorus; after air had been injected to clear it, gastric samples were removed, and the tube was withdrawn to its former position and reconnected to the apparatus.

* Drip of olive-oil emulsion.

Table IV summarizes the findings by this method. A drip of water was taken as a control, and, as was to be expected, it caused no significant alteration to the curve resulting from diet alone; bovril was similarly inactive. The acid-depressant action of olive oil was again in evidence: both undiluted and in emulsion form it reduced the general level to a considerable degree, although the minimal readings were still about 20 units. With both milk and a suspension of aluminium hydroxide (aludrox) the results were remarkably constant and effective; they regularly obliterated free acid, and one case was noteworthy in that no readings after the first were above the base-line. Chart III illustrates curves from one patient, and shows the effects of milk and aluminium hydroxide.

CHART III.—Hourly free acidity of gastric contents over 12-hour periods in one case on the "ulcer diet" with continuous intra-gastric drip. (a) i..... diet alone; ii..... diet plus aluminium hydroxide drip. (b) iii..... diet plus olive oil drip; iv..... diet plus milk drip.

It can be concluded from this part of the study that with chosen substances, used by a continuous-drip method—for example, milk and aluminium hydroxide—an effective control of hyperchlorhydria is obtained. An explanation is required, however, for the comparative failure of olive oil to do so alone, and some possible reasons are set out below.

Discussion

An investigator reporting alterations to gastric acidity in peptic ulcer must consider (a) the mechanisms involved in such alterations, and (b) their relation to healing. The factors concerned in the former are: (1) the motility of the

stomach; (2) the diminution of acid secretion; and (3) the neutralization of acid juice already produced.

Specimens taken an hour after the introduction into the stomach of any substance (especially in fluid form) do not show the changes in acidity which occur immediately, and by the end of an hour a rise in acid level may have taken place, whereas there had been immediate depression or neutralization. This may well explain the results with bovril and meat soup (Group I) and the initial fall in acidity with milk reported by Nicol (1930).

The present work was concerned, however, not with the immediate reaction to any food, but with the general effect over periods of prolonged feeding. The experiments indicate that there is no continued lowering of acidity when feeds are given two-hourly, in which circumstances a meal passes out of the stomach too rapidly for efficient neutralization because of enhanced motility, fresh secretion accumulating to raise the acidity of the emptying stomach to its previous high level. The initial fall after food may also be partly accounted for by dilution.

The continuous drip of milk induces a constant neutralization, enough milk being left to control the constant acid secretion, and this process can be maintained indefinitely. The effect is also obtained by the continuous drip of aluminium hydroxide, the properties of which, and of its pharmacological ally magnesium trisilicate, have been investigated very fully by many workers: to mention a few, Einsel and others (1932, 1934), Adams and others (1936), Emery and Rutherford (1938), Adams (1939a, 1939b), Bennett and Gill (1939), McIntosh and Sutherland (1940), in the case of the former; and, in the latter, Mutch (1936), Mann (1937), Kraemer (1938), Kraemer and Aaron (1940), Reid (1939). Experiments show that these agents neutralize HCl more slowly than do other alkalis, and from clinical experience their antacid effect is known to be spread over several hours.

Why should olive oil reduce acidity to a greater extent when given as a food (Group I) or added to the diet (Groups II and III) than when supplied continuously (Group IV)? If the hypothesis mentioned above holds good the explanation must be that oil has little acid-neutralizing power, and that its effect is in the main due to control of the other factors involved in the maintenance of acid level—namely, reduction of actual secretion and diminution of gastric motility. It is believed by many that the problem of motility is an important one, and that it throws light on the inconsistent results often obtained.

It is evident that undue stress has been laid on reduction of HCl alone as a necessary provision for the healing of gastric ulcers. Brown and Dolkart (1937, 1939) find that fluctuations in gastric acidity bear no relation to the onset of recurrence. Bloomfield and French (1938) obtain no correlation between healing and acidity, as measured by the "basal secretion" method. Wosika and Emery (1936) report that although the Sippy regime is effective in controlling acidity, they could demonstrate no relation between symptomatic relief and effectiveness of neutralization; while Steigmann and Fantus (1940), in their investigations of various antacids, showed that relief of pain could easily be produced, but that lowering of acidity occurred in less than one-quarter of their cases. Their conclusion is that ulcer therapy should not be based solely on methods of decreasing gastric acidity. The majority of these investigators, however, refer to acid levels before and after some particular application of treatment, and it is well known that hyperchlorhydria cannot be permanently cured by medical means. The matter is summarized by Mann (1930), who affirms that the important factors in the development of a peptic ulcer are chemical and mechanical. Healing always begins immediately after the surface is

protected from the acid gastric contents. The attainment of a low acid level is only one method of realizing this; such an effect is most completely attained by neutralization of the gastric juice as soon as it is secreted, a process which can only be carried out effectively at present by means of the continuous intragastric drip apparatus. This, however, is not a practicable method for the vast majority of cases, and should be reserved for those of especial severity.

The question of gastric motility in cases of ulcer would appear to be the problem of the future, and the next step ahead seems to be the discovery of some practical means of ensuring continuous diminution of gastric motility. Olive oil does not supply this want, and the continuous intragastric drip, as has been indicated, will not fulfil the condition of practicability. The purpose of further research must be to find some more effective method.

Summary

An investigation into the effects of various foods and simple drugs on the gastric hyperacidity of peptic ulcer is recorded, particularly with a view to prolonged acid reduction.

Certain foods, notably milk, when given two-hourly, have little persistent neutralizing power; these foods, although diverse in nature, produce similar acid levels.

Olive oil is strongly acid-depressant when supplied as a food or given before meals.

Considerable reduction of acidity results from a combination of oil and alkali with a suitable diet which by itself is ineffective.

The continuous intragastric drip apparatus provides at present the only means of constantly maintaining a low acid level. Milk and aluminium hydroxide are most effective in this method; oil is less so.

The mechanisms of these alterations in acidity are discussed.

Some considerations of the relation of acid control to healing of an ulcer are examined.

Investigation of alterations in gastric motility—i.e., some method of controlling the emptying of the stomach so that remedies are retained to ensure continuous neutralization of acid as it is formed—is suggested as perhaps the most important problem requiring further study in the treatment of peptic ulcer.

This work was performed in the Gardiner Institute of Medicine, Glasgow University and Western Infirmary, during the tenure of a Carnegie Medical Research Scholarship, which was interrupted owing to war service. I wish to express my gratitude to Prof. J. W. McNee for his constant advice and helpful criticism. I have to thank Messrs. John Wyeth and Brother, Ltd., for a supply of aludrox, and for the continuous intragastric drip apparatus.

Medical Memoranda

Interstitial Subcutaneous Emphysema complicating Pulmonary Tuberculosis

After reading the case report by Dr. T. B. L. Bryan in the *Journal* of December 21, 1940 (p. 868), I looked up the records of a case which was under my care in the Sanatorium Pavilions, City Hospital, Walker Gate, Newcastle-upon-Tyne.

CASE RECORD

The patient, a man aged 27, was first seen by me in consultation in his home on April 21, 1936. He gave a history of not being well for about four months, the last five weeks of which had been spent in bed. There was no history of tuberculosis, but three years previously he had had an operation for a rectal abscess. The family history with regard to tuberculosis was bad. A sister was a sputum-positive case of pulmonary tuberculosis; a brother who had been a sputum-positive case of pulmonary tuberculosis died in 1934, and another brother who had been a sputum-negative case of tuberculosis died in 1919. The home conditions were poor; the family of three lived in a two-roomed tenement.

On examination the patient was pale and ill and his general condition was poor. He had impaired percussion over both sides of the chest, with crepitations more pronounced on the right. He was admitted to hospital on April 22, 1936. While there his temperature varied between 99° in the mornings and 103° in the evenings, and his pulse was rapid, usually about 120. A radiograph showed very widespread scattered densities in both lungs, with cavitation in each upper zone below the clavicles. His sputum was negative for tubercle bacilli. On April 25 he suddenly developed emphysema of the tissues of the neck and upper part of the chest and back. This caused some dyspnoea. A radiograph taken the same day showed a small left lateral spontaneous pneumothorax and also the air in the tissues of the neck. He was then transferred to the Newcastle General Hospital to see if surgical intervention could assist him and perhaps lessen the dyspnoea and distress. It was, however, decided that he would not be benefited by any operation, and he was brought back to the City Hospital on May 1. He continued to retrogress, and he died on May 31, 1936. The surgical emphysema which persisted until his death was limited to the neck and chest in its upper half. Permission for a post-mortem examination was not obtained.

COMMENTARY

This patient, who had extensive acute pulmonary tuberculosis, developed a left spontaneous pneumothorax and, at the same time, subcutaneous emphysema of the tissues of the neck and upper half of the chest. Spontaneous pneumothorax as a complication of pulmonary tuberculosis is common, but subcutaneous emphysema is a much rarer condition. Since I became associated with the Sanatorium Pavilions in 1923 there have been 6,266 admissions of cases of pulmonary tuberculosis and 1,512 deaths. The case recorded is the only one that has developed subcutaneous emphysema.

Fishberg (1932) states that interstitial subcutaneous emphysema is not unknown in acute pulmonary tuberculosis and is very rare in chronic tuberculosis. Meade and Stafford (1930) review the condition and describe some cases, but it is not often recorded in medical literature.

I am indebted to Dr. J. A. Charles, medical officer of health for Newcastle-upon-Tyne, for permission to publish this case.

GEORGE HURRELL, M.D., D.P.H.
Tuberculosis Medical Officer, Newcastle-upon-Tyne.

The wisdom of subsidizing private growers of cinchona in India is being urged by the Indian Chemical Manufacturers' Association, which points out that if efficient anti-malarial treatment is to be provided in India, at least 6 lakh lb. of quinine will be required annually. The present consumption is about 2 lakh lb., of which India produces about 70,000 lb., the remainder being imported from abroad.

Reviews

CHINESE MEDICAL THOUGHT

The Chinese Way in Medicine. By Edward H. Hume. (Pp. 190 \$2.25 or 14s. net.) Baltimore: The Johns Hopkins Press; London: Oxford University Press. 1940.

Dr. E. H. Hume was connected with the Peking Medical College of the Rockefeller Foundation and became first Principal of the Yale Medical College in China. He had a gift for cultivating Chinese friendships which gave him ample opportunities for discussing the merits and demerits of the age-old empiric system of medicine as compared with modern scientific medicine. From the records of the Shang Dynasty (1766-1122 B.C.), which saw the evolution of early concepts of the oneness of all life, a group of metaphysicians sprang up who gave form to the prevailing ideas of still earlier years and taught that the phenomena that make up health and disease related to the universe as a whole. They contended that the life of man in all its phases is inseparably linked with every other form of life, whether of animals and birds, of trees and plants, or even the less perceptible life of material things. Empiricism in China was a blind acceptance of traditional beliefs as against independent inquiry.

Dr. Hume's book is a survey of a system of Chinese medical thought which is philosophical in conception and has evolved practical procedures of real value for both diagnosis and treatment. The author thinks that this system, far older than Greek or Arabian medicine, has proved adequate to the needs of an Eastern Asiatic civilization. He deals with three aspects of his subjects: (1) the universe and man in Chinese medicine; (2) the founders and conspicuous exemplars of Chinese medicine; (3) some distinctive contributions of Chinese medicine. High up among China's contributions of permanent value is the establishment of medical libraries and the preparation of special monographs. One compiler has estimated the number of known medical books at 12,600 volumes. Nor did medicine find itself concerned with theory and practice only. The legal aspects of the profession's task were also faced frankly. A volume published during the Sung Dynasty (A.D. 960-1279) was the one recognized coroner's handbook before the establishment of the Chinese National Health Administration in 1927.

In reading this book the thought frequently occurs that "there is nothing new under the sun." The Chinese had practical inoculation against small-pox from the sixth century A.D. Gonorrhoea was known and accurately described from the earliest times, but syphilis was not introduced to China till A.D. 1505. A manual on obstetrics and gynaecology published in A.D. 1661 laid special stress on pre-natal treatment. Ephedrine (ma-huang) has long been known to the Chinese, as also chaulmoogra oil for leprosy. These are but a few of many noteworthy points. The volume is interesting and informative throughout and concludes with a good bibliography which gives evidence of much painstaking research by the author.

PRACTICAL DERMATOLOGY

Dermatologic Therapy in General Practice. By Marion B. Sulzberger, M.D., and Jack Wolf, M.D. (Pp. 675; illustrated. 22s. 6d., or \$4.50 post paid.) Chicago: The Year Book Publishers, Inc.; London: H. K. Lewis and Co.

Dermatological therapeutics are so intimately bound up with diagnosis that any work on skin treatment must devote a large space to questions of diagnosis, and this book is no exception, but being intended for general practitioners it almost exclusively deals with the commoner affections of

the skin after an opening essay of considerable length on value on the general principles of dermatologic therapeutics which most practitioners will find very useful.

There is one very good illustration of the extent to which cutaneous treatment is bound up with diagnosis, and this is the admirable chapter on the management of drug eruptions. This is devoted for the most part, as it must be to the detection of the peccant drug—in other words to the diagnosis of the eruption. The chapter is well illustrated and there are some excellent tables to assist the practitioner in making his diagnosis, but the space devoted to actual therapeutic measures is small. After all, the only therapy needed in 90% of drug eruptions is the discontinuance of the drug which is doing the mischief. These considerations lead us to doubt whether it is really legitimate to label books as ostensibly devoted solely to cutaneous therapeutics. In our experience the more valuable such works are the greater the proportion of space devoted to diagnosis. We really fancy that the fundamental reason for bringing the suggestion of therapy so prominently into the title is to offer a special attraction to the practitioner appealing to his well-known (and very natural) hunger for help in treatment.

It is always interesting to note the peculiarities of terminology in American writings. Our transatlantic brethren are never afraid of a new word (whether it be needed or not!), and here is one which certainly is a new one to us in this connexion, and that is an "id." It appears that an "id" is an eruption which is secondary to a fungoid infection of the skin and is a convenient abbreviation for such clumsy terms as dermatophytid, trichophytic etc. It certainly has the merit of brevity. Very sensible Sulzberger warns the practitioner against the too facile diagnosis of fungoid infection of the skin, a diagnosis which, as he says, has been much overdone of late years. He points out that the management of the "ids" require considerable tact, as their behaviour closely resembles that of ordinary eczematous dermatitis, and the employment of gross antifungoid remedies (for example, iodine) often merely causes a regrettable exacerbation of the eruption. This may happen even when actual mycelium has been found on the feet or elsewhere, and when there is a positive reaction to trichophytin skin tests. The habit, so common at the present time, of diagnosing an "id" without such positive evidence of fungoid infection he greatly deprecates.

Altogether this book is much to be commended as a clear exposition of practical modern dermatology. It is a sound guide to the family physician and there are few dermatologists who will not glean useful hints from its perusal.

BIOCHEMICAL CLASS WORK

Laboratory Manual of Biochemistry. By Benjamin Harrow, Ph.D., Gilbert C. H. Stone, Ph.D., Ernest Borek, Ph.D., Harry Wagreich, Ph.D., and Abraham Mazur, Ph.D. (Pp. 119; 19 illustrations. 7s. 6d.) Philadelphia and London: W. B. Saunders Company. 1940.

Prof. Harrow's laboratory manual describes an up-to-date course of carefully selected class experiments. Starting with the usual qualitative tests and experiments the course leads on to a number of well-chosen quantitative estimations. The experiments are so carefully described that the student should have little excuse for failure in their performance. Although the authors make no such claim the course is well suited to medical students. The book is certainly one which merits careful examination by teachers of practical (animal) biochemistry and which they will be tempted to keep on their shelves. It is a ideal practical book for class use and is offered at a reasonable price, for its 119 pages are well filled and there is no superfluous descriptive matter. Even in the hands of students the wire-O binding should survive the course.

While the reviewer has nothing but praise for the book as a whole, there are a few curious omissions. Blood spectra, pyridine-haemochromogen crystals, Fehling's test, and Harrison's test for bile pigments are not mentioned. The student is frequently instructed to examine and draw crystals; it would have been more helpful to provide good drawings or photographs of these crystals in place of the illustrations of Kjeldahl's apparatus and a colorimeter. But these omissions are easily made good by the teacher and do not detract from the value of a book which is certainly among the best of its type and merits a wide circulation.

A MISSION DOCTOR IN THE CONGO

Congo Doctor. By W. E. Davis, M.D. (Pp. 286; illustrated. 12s. 6d. net.) London: Robert Hale, Ltd. 1941.

The greater part of Dr. Davis's book deals with the people, white and native, who inhabit the Coquilhatville Province of Belgian Congo. When the author left the U.S. Marine Corps, in which he served in the last great war, he resolved to devote himself to missionary work. So he went to college and, while there, met the girl who later became his wife and persuaded him to be a mission doctor in the Congo. The result surpassed any dreams he had ever had, and his ten years in the jungle were a tremendous experience that he never regretted. Judged by our present-day standards the Congolese are a backward people, for they have no need of progress, living as they do in a region where very little effort is required for subsistence. Nature is adequate and calls for but a minimum of work from her creatures. Hidden away in the dense fastnesses of their tropical woods they lead the simple life, and time has no significance for them.

The author led a busy professional life; during his last year at Lotumbe over 65,000 patients came to the hospital dispensary, and he performed 536 major operations with a mortality of less than 1%. He had his full share of dramatic cures: he notes that "there is nothing more striking in medical therapy than the effect of neosalvarsan on a full-blown case of yaws. The foul disgusting yellow pustules which cover the entire body of the sufferer frequently fade away in the course of a few days. One might almost say they disappear before one's eyes." He had many cases of enormous elephantiasis of the scrotum; "hundreds and who had scarcely walked for years and returned to their villages able to lead an active life."

The book is an encouraging account of the opportunities for great good which a capable and self-reliant medical man can find in a primitive country. The author speaks well of the Belgian Colonial Administration, and gives graphic word pictures of the jungle forests and their inhabitants.

Notes on Books

Dr. J. W. FISHER's little book, *Psychology and Mental Disorders for Nurses*, is meant to be a refresher for mental nurses preparing for their examinations. The first part is a survey of normal psychology which is rightly rather fuller than the next, since without the fundamentals the practical issues of a subject cannot be comprehended or successfully put in practice. It is always difficult to know how much nurses can understand in their reading, and of necessity abbreviation means that simplicity and clarity are to some extent sacrificed. Most nurses have neither time nor energy after their day's work to read much, and some books will be too long and others too concentrated to be useful to them. Whether the present volume, which in addition to normal psychology covers the whole field of mental illness as well as practical hints for mental nurses, will steer between these two extremes is for the nurses themselves to decide, but it is a clear compact little book which should be useful at least to some of those for whom it is written. The publishers are Edward Arnold and Co. and the price is 4s.

Preparations and Appliances

AN APPARATUS FOR CONTINUOUS OR INTERMITTENT ADMINISTRATION OF PENTOTHAL SODIUM SOLUTIONS

RODERICK A. GORDON, B.Sc., M.D., D.A., Captain, Royal Canadian Army Medical Corps, writes:

The apparatus described below is designed with three purposes in mind—namely, (1) to provide a means of continuous or intermittent administration, over considerable periods of time, of pentothal solutions which would keep the needle patent and allow the anaesthetist freedom to attend to the airway, blood pressure, and pulse determinations; (2) to give rapid control of anaesthetic level; (3) to provide a portable apparatus which can be used for several patients in succession without the necessity for re-sterilizing the whole of it and without the need for mixing fresh solutions for each patient.

The apparatus, shown in Fig. 1, consists essentially of two bottles, one containing normal saline and the other pentothal

FIG. 1.

sodium solution, connected through independent drip bulbs and rubber tubing to a Y adapter fitting to the intravenous needle. The rubber bungs in the bottles are arranged to lock in, and the solutions are delivered by pressure applied to the bottles through a Y connector by a rubber bulb syringe. Flow is controlled by a screw pinch-cock on each tube, placed between the bottle and the drip bulb. The whole apparatus is arranged to fasten on to a stand, and is readily removed for boiling. The stand has a cover which clips on like the cover of a portable typewriter, and makes it possible to transport the whole apparatus after sterilization (Fig. 2). Two adapters are provided (Fig. 3), each attached to two short lengths of rubber tubing, the tubing having glass windows in the form of short glass connectors.

The interchangeable connector allows the apparatus to be used for several patients in succession without the necessity for re-sterilizing the whole equipment. The glass windows are used to determine any flow of blood back through the needle. If blood is allowed to back up past the interchangeable length of tubing it becomes necessary to wash and re-sterilize the whole tubing.

This arrangement allows the delivery of either the pentothal or saline solution simply by turning the screws of the pinch-cocks, adequate pressure in the bottles being maintained by occasionally squeezing the rubber bulb. The level of anaesthesia is controlled with a minimum of lag by the use of the double tubing to the Y adapter, thus cutting down the "dead space" to the volume of the adapter and needle.

We have used this apparatus with success during the past six months, both for inducing and maintaining anaesthesia for surgical procedures lasting up to two hours, and to keep

FIG. 2.

FIG. 3.

patients asleep during procedures undertaken with spinal anaesthesia or regional blocks. We prefer, after this amount of experience, to use a 2% solution for maintaining full anaesthesia, and a 1% solution to maintain light anaesthesia in association with blocks. In addition to the obvious technical advantages of the method there is a considerable saving in the amount of drug used per unit time of anaesthesia.

Nova et Vetera

CHLOROFORM IN THE 'EIGHTIES

HINTS TO YOUNG ANAESTHETISTS

Many young doctors, during this war, will be called on to administer chloroform to patients and may feel not too confident over the business. Having given chloroform or seen it given for well over fifty years, I offer a few hints to junior colleagues. My impression is that the art of giving chloroform is passing away. The surgeons to the Glasgow Western Infirmary about fifty years ago never seemed to have deaths from chloroform. In a debate on the subject, about that time, under the chairmanship of Dr. William Macewen (later Sir William), Prof. Macleod stated that up to that point he had never had a death from chloroform. Macleod used a folded towel placed over the face, with his finger lifting the edge of the towel away from the mouth about one or two inches; he gave the chloroform, to begin with, slowly. Thus Macleod, in roughly 10,000 cases, had no deaths from chloroform. I believe the same could be said of Prof. George Buchanan, Hector Cameron, and Alexander Patterson, all contemporary surgeons to the Western Infirmary.

The Glasgow Tradition

Buchanan allowed his students to give chloroform, and they unwittingly showed us how not to give it. Time and again I have seen Buchanan run and dip the end of a towel in cold water and vigorously slap the patient's bare chest two or three times. The effect was magical, the patient suddenly sitting upright on his haunches and looking round bewildered. If a patient collapses under chloroform, becoming pale from heart failure, Buchanan's method should be at once adopted, along with sudden inversion of the body, by getting the lower end of the table thrown up into the air. These two measures alone will frequently save life. In the discussion alluded to, reported in the *Glasgow Medical Journal*, Dr. Walker Downie referred to a case of Marion Sims's, in Paris, where the patient collapsed and the great surgeon Nélaton advised inversion of the body. When the body was inverted recovery took place; but inversion, with artificial respiration, had to be maintained for an hour and a half. I have had occasion to use Buchanan's method of the

wet towel in patients brought into a police office, comatose from whisky, and found it most effective in about ten to fifteen minutes.

The pulling out of the tongue with forceps I look upon as an indication of faulty administration. The secret of giving chloroform is not to give it too concentratedly in regard to the oxygen of the air. I fancy if chloroform were given slowly and sufficiently diluted with oxygen it could almost be given *ad libitum*. Lister stated that Syme, the great Edinburgh surgeon, never had a death from chloroform up to the end of his operating career. Macleod taught his students to watch the breathing, the colour of the lips, and the pulse. The great danger of chloroform—which in my opinion arises from too large a dose at a given time and in reference to the oxygen—is heart failure.

For practical purposes the young medical man should confine the dropping of his chloroform on to one of the lower quadrants of the mask, and on no account splash it over the whole mask. If possible a small bottle of ether should be carried as well as the chloroform; and if the patient begins to turn pale ether should at once be substituted for chloroform. For asphyxia, artificial respiration, pulling out the tongue, venesection, etc., will be resorted to. But such complications can be prevented.

Dornoch.

J. T. MACCACHLAN, M.D.

MORE OLD MEDICAL BOOKS

Hard upon the dispersal of Sir D'Arcy Power's library come some more opportunities for medical book collectors. Messrs. Sotheby have been selling a library, largely botanical, which included Culpeper's *English Physitian*, 1st edition, 1652; Dodoens's *Nieuwe Herball* . . . now first translated out of French into English by Henry Lyte, black letter, 1578; the *Grete Herball* which geuth partly knowledge and understanding of all manner of herbes . . . for they hele and cure all manner of diseases and sekenesses, Southwarke, Peter Treveris, 1526; Jerome of Brunswick's *Noble Experyence of the Vertuous Handyworke of Surgeri*, black letter, 1525; another similar treatise on herbs by the same author, 1527; and William Turner's *Herball*, 1568, with a Booke of the bath of Baeth in England, bound up with Jerome of Brunswick's most Excellent and Perfecte Homish Apothecarye, translated out of the Almaigne Specche by Jhon Hollybush [i.e. Miles Coverdale], black letter, 1561.

Messrs. Davis and Orioli, now of Wallingford, lately of Bloomsbury, have issued a long catalogue of old medical books, only a few of which can be noted here. Alexis of Piedmont's *Secretes*, translated into English by William Ward, the three parts bound together (1560, 1563, 1566), is offered at £15 15s. Philip Barrough's *Methodo of Physicke*, 1583, went through many editions: the first one is of the greatest rarity, and a copy of it is priced at £48; little is known of the author beyond the fact that he graduated in surgery at Cambridge in 1559. Andrew Boorde's *Breviarie of Health* is represented by an edition of 1575; Sir Thomas Browne's *Religio Medici* by the second edition, of 1645. An interesting item is the Playbill of the Edinburgh Pantomime of January, 1848, which mentions "Doctor Chloroform's Establishment" and goes on to refer to the "new anaesthetic agent, Sulphuric Ether," listed at 15s. Sir T. Elyot's *Castell of Helth* is a reprint, probably of 1560, though it has the title page of the original edition of 1534. The original recipe for Dover's powder, not quite the same composition as that which now passes under this name, is contained in the Widow Bradley's *Ancient Physician's Legacy to his Country*, 1733; another widow whose book is of some interest is Mrs. John Hunter, who published a volume of poems in 1802; the copy now offered is inscribed by the great surgeon's relict on the flyleaf . . . perhaps the only one of her poems which is still familiar is the lyric, "My mother bids me bind my hair." John of Gaddesden (1280-1361), physician to Edward II, is represented by the rare fourth edition of his famous textbook, 1595: it was first published in 1492. An "association" copy of a century ago is an issue of Townsend's *Physician's Vade Mecum*, with autograph of John Snow on the title page and 28 pages of his MS. at the end, giving details of his professional work in London from 1838 onwards: he is best remembered as one of the earliest pioneers of the scientific study of anaesthesia, which he administered to Queen Victoria at the birth of her two youngest children (one of whom, H.R.H. Princess Beatrice, is still alive) to the scandalization of many narrow-minded pietists.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JULY 5 1941

CHEMOTHERAPY IN ACUTE OTITIS MEDIA

Harvey Cushing once pointed out that progress in medicine occurs mostly by fission, and that special departments and groups, once they are strong enough to be independent, seldom fuse either with one another or with the parent body. He revealed a proposal for the creation at Johns Hopkins University, on the resignation of Osler, of a *super*-professorship of medicine to keep all the departments in contact and in proper relationship with one another. The scheme never matured because W. H. Welch, who was asked to undertake the task, refused; but it is not difficult to see what influence the holder of such a position might exercise. One matter that would certainly occupy his attention to-day would be the control of acute bacterial infections by chemotherapy. Every clinical department, both general and special, has turned eagerly to the new resources. Enthusiasm and sometimes lack of judgment have been manifested, so that the abuse of chemotherapy has become as important a subject for inquiry as its use. A speaker in a recent debate named the quantity of the new drugs which had been dispensed in one year in a large hospital in London, and the figure was so large that it is impossible to avoid the conclusion that a respectable fraction must have been misapplied. This is probably the state of affairs in many other hospitals. The early and most spectacular successes with chemotherapy were in cases of septicaemia, mostly obstetrical in origin; but such cases are sometimes otogenic, and aural surgeons soon found that not only septicaemia but also meningitis could be controlled, and that recovery could become commonplace in cases which a few years ago would certainly have been fatal. Recovery, however, if no longer a miracle, is still not the end of every case. Why should there be failures? How and to what extent should chemotherapy be used in those early infections where complications have not yet arisen and the trouble is likely to be self-limiting?

The answer to the first question is twofold. It is necessary to be certain that the infecting organism, both in the primary focus and in the area to which the complication has extended, is one which may be expected to yield to the treatment. Clinical examination, however careful and frequent, is nowadays not enough. Bacteriological examination is essential so that the appropriate drug, if there be one available, may be administered. Generally sulphanilamide is chosen, but in a pneumococcal infection it may be necessary to change to sulphapyridine or sulphathiazole. Secondly, the treatment cannot succeed in the presence of a collection of undrained pus or if there is an infected thrombus anywhere in the area concerned. It is no use demanding

the impossible of these drugs, and to employ them in such circumstances only brings discredit on a potent remedy; for either the patient will die unrelieved or there will be a temporary but only apparent clinical improvement which masks the real state of affairs. In the latter case the complication will ultimately prove fatal, even if it seems to disappear, as in the case of meningitis, for it will be fed afresh from the primary focus of suppuration if this is not eliminated. The treatment required may vary from a simple paracentesis of the tympanum to an extensive mastoid operation. If there is a venous thrombosis the clot need not, in theory, be disturbed so long as it is aseptic; but how often this occurs may be guessed from the usual clinical history of such cases. In practice it should be removed until there is free bleeding from each end of the opened sinus. If it extends downwards out of reach to the jugular bulb there should be no hesitation in tying and dividing the jugular vein in the neck, so that the bulb can drain when the ligature is removed from the upper end of the vein. It seems remarkable—even taking for granted the potent effect of the appropriate drug on each organism—that in purulent streptococcal or pneumococcal meningitis so many recoveries ensue, for the ease with which a collection of pus may become entangled in the meshes of the arachnoid must be a severe handicap upon the action of the drug. It may be, therefore, that a basal meningitis, on account of the size of the cisterns, is more prone to resolution than a meningo-cortical extension, which would easily become encysted and localized into an abscess. For this reason a very high percentage of recoveries from meningitis can be expected only when the treatment is administered at an early stage.

Chemotherapy has proved its worth under desperate conditions. The next question is how and to what extent it should be used in early infections that are likely to be self-limiting and which might recover spontaneously or with simple, old-fashioned treatment. Once an acute infection of the middle ear has been initiated it is impossible to predict what its course may be. It is therefore wholly reasonable to adopt a treatment that may shorten its duration and, by promoting early resolution of the inflammation, give protection against complications. That chemotherapy can do this is not merely a general clinical impression: the figures of Horan and French¹ give satisfactory proof. In a series of 607 cases from 1934 to 1937 there were 138, or 22.7%, needing the mastoid operation. In 621 cases treated by chemotherapy from 1937 to 1939 only twenty-one, or 3.4%, required operation; there were no deaths in the second series. Wesley Bowers² has produced similar evidence. In a series of 793 cases, 396 were treated by chemotherapy. He found that both the duration of the discharge and the proportion of patients needing mastoid operation were reduced in this way by 50%.

The statistics of Horan and French present two convincing features. The numbers of the control series and the experimental series are nearly the same, and the clinical material is of a homogeneous character, being drawn from the personnel of the Royal Navy. Not only is the number of mastoid operations materially reduced, but the absence of any fatality is strong evidence of protection against complications. There is, therefore, justification from the evidence (supported by the observation of Wesley Bowers) for administering

¹ *Lancet*, 1940, 1, 680.² *J. Amer. med. Ass.*, 1940, 115, 178.

either sulphanilamide or sulphapyridine in acute otitis media. But this is not to be done in a casual manner, for although the administration is an exceedingly simple matter it is not without some risk. Here again it is necessary to know the nature of the infecting organism if it is to be made certain that an appropriate drug is available for administration. It is no excuse to plead that because the tympanic membrane has neither ruptured nor been incised there is no discharge to examine. The infection comes from the nasopharynx, and material taken from there will give the bacteriological diagnosis. In any case discharge collected from the meatus is liable to be contaminated from the skin.

In all statistics the majority of infections are shown to be streptococcal, though the pneumococcus is nevertheless frequently found. T. B. Layton has divided the infections of the middle ear into the nasopharyngeal and the cutaneous—the former travelling by the Eustachian tube and the latter reaching the tympanum from the skin of the meatus through a perforation. This assumes that the primary infections are streptococcal and pneumococcal, while the *Staphylococcus aureus* is a secondary infection from the meatus; along with it go a number of other organisms, including *Staphylococcus albus*, *B. coli*, *B. proteus*, and *B. pyocyaneus*. The latter are no doubt secondary invaders. But the question which is difficult to settle is whether the *Staphylococcus aureus* attacks the middle ear as a primary nasopharyngeal infection. E. P. Fowler² of Columbia University, in a series of 2,775 cases in the years 1933 to 1939, found pure cultures of staphylococcus in 36.7%. This is far higher than most authors report, and suggests contamination in taking material from the meatus. It is probable that the *Staphylococcus aureus* is occasionally the primary organism (but much more rarely than Fowler suggests), and that it easily overgrows and masks the primary organism in cultures from the meatus. Certainly it is remarkable how constantly the *Streptococcus pyogenes* is found by the bacteriologist when the culture is made at an operation from pus in the mastoid process or—what is the only absolutely satisfactory method—from chips of bone. This explains the frequent success of sulphanilamide given empirically, though it affords no justification for neglecting bacteriological examination or for not taking care to avoid contamination in collecting material for the laboratory.

The general risks attaching to the administration of these drugs—such as gastric intolerance, leucopenia, and occasionally agranulocytosis—are well known and concern only the exceptional patient. It is perhaps not practicable to obtain blood counts in every case, but if the clinical course is not satisfactory and suggests unusual sensitiveness, which is naturally beyond control, the blood examination should certainly not be omitted. There does, however, appear to be a decided though easily controlled risk arising from insufficient dosage. This insufficiency may come about either by administration in too small quantity (which for an adult should be 2 grammes as an initial dose—continued at the rate of 1 gramme every four hours, taking the age and especially the weight of the patient into consideration), or by administration over too short a period (which should extend to two or three days after all clinical signs have disappeared). If the administration is

stopped too soon there may be either a relapse or a subsidence of symptoms, masking incomplete resolution and leading to complication later. Repeated examination of the ear is essential; if the patient is in pain or the tympanum is seen to fill with fluid under tension, paracentesis should not be withheld in the hope that the process will resolve without spontaneous perforation of the membrane. The neglect of paracentesis at the right time may be a factor causing either incomplete resolution and an adhesive otitis with subsequent deafness, or the need for a mastoid operation. Unless these precautions are observed and the patient is kept in bed, it is better to employ the ordinary methods of treatment only. Fowler recommends that treatment by chemotherapy should begin a week or ten days after onset if the patient does not seem to be getting on well without it. It seems reasonable, however, to begin the treatment as early in the course of the illness as possible under the conditions already mentioned. If the best results are to be obtained from the drugs used in chemotherapy their limitations must be recognized and they are not to be regarded as a panacea for all acute infections. The drugs are so powerful that the early results seemed to border on the miraculous, but this is no excuse for using them in a casual way: their very potency demands that they be used in the most efficient manner available.

WAR NEUROSES

The late Dr. T. A. Ross had probably a higher reputation as a psychotherapist than any other doctor in the country, and his book, *The Common Neuroses*, is already a medical classic. In a little book, *Lectures on War Neuroses*,¹ published posthumously, he gives in brief and simple form the fruits of his experience in the last war and since; before he died he had been applying his knowledge to the cases he saw in this war. Ross was a man of independent mind and irreproachable integrity, with no axe to grind. He had learned his methods in a very practical school—the school of his own experience. They were not coloured by any special form of training or adherence to any particular doctrine. It would be a mistake to suppose that he relied only upon personality and common sense, although he had both in uncommon abundance. His methods, as they appear in this book, could certainly be simple; but they were always most systematic and logical, the result primarily of the quality of his own mind and secondarily of his appreciation of the methods of both Dejerine and Freud. They were reinforced by an acute intuitive perception of the foibles of human character, and he did not hesitate to admit that in certain cases his own methods were not enough and had to be supplemented by something as near a psycho-analytical technique as he cared to compass. He reiterates in this book that there is a real difference, not one of degree only, between what is called a "neurosis" and a "psychosis." He found from his experience that on the whole the two conditions behaved very differently from one another in his hands, whether he cured them or not. The onus of proving the opposite rests upon those who, without his therapeutic achievements to their credit and with no

¹ *Lectures on War Neuroses*. By T. A. Ross, M.D., F.R.C.P. London: Edward Arnold and Co. (5s.)

published writings illustrating the use of the "common-sense method" in psychoneuroses in general, claim that this method is as effective as any other.

Ross was not burdened in his efforts by haunting thoughts of constitutional factors. He recognized their existence, as he does again in these lectures; but he was interested mainly in what he could work with and could influence in his patients. He stressed the greater susceptibility of such people to psychological illness, while insisting that what made them fall ill was often faulty upbringing and mistaken handling of personal situations, both of which can be modified by psychotherapeutic re-education. "Even if he had a bad heredity, that was all the more reason why he should have a good education." There is one point in which Ross's remarkable memory may have deceived him. He records that Weir Mitchell was led to the idea of his rest cure by seeing cases of exhaustion in soldiers of the American Civil War. Osler² at any rate gives a different account, citing chapter and verse for the story. He says that Weir Mitchell was prompted to the discovery by despair at not knowing what else to suggest when confronted by a woman patient who had been prescribed everything except rest.

Ross comments adversely on the use of the term "shell shock" and regards "effort syndrome" as a no less unfortunate label for the "D.A.H." of the last war. He understood discipline as a factor in the treatment of neuroses, especially when they are determined by a primitive desire to escape responsibility, as so many war neuroses are. There was a superior officer of Ross's in the last war who remarked that discipline lay in his hands only, and that Ross was wrong in forbidding patients with hysterical fits to go out of hospital to parties. He hints dryly that under this regime the incidence of fits rose again. Nevertheless, Ross was tolerant towards both coward and malingerer. "Cowardice is a military and not a medical category," and, as he said, we have not solved our problems by calling a man a malingerer, but should try to find out why he is one. Having been a family doctor for many years himself, he wanted the family doctor consulted for a previous history of each recruit. On the recruiting board itself a specialist was required, he argued, to assess what should be done, although the specialist could not hope to be one hundred per cent. right. In particular the motive for joining, and especially for seeking a commission, should be ascertained. His third point was that battalion medical officers should look out for signs of strain, and he mentions the findings of the Shell-shock Commission after the last war, which are not sufficiently remembered. The battalion M.O. should take his equal share in the risks and hardships of the men, and commanding officers should recollect that even the best man can be sent too often to a dangerous task. The best psychiatric prophylaxis is done, Ross felt, by the battalion medical officer among the healthy men who are going on with their jobs, and not in special camps behind the lines. He points out something that responsible authorities should remember now: that it is going to be much more difficult to cure war neurotics at the end of the war if return to civil life means return to unemployment. It is a pity that Ross's humanity and skill are lost to us now, except in his writings, and that this little book must be his last.

² *Life of Osler*, by Harvey Cushing. Oxford, 1925.

VITAMIN B₁ DEFICIENCY

It has been recognized for many years that the breakdown of pyruvic acid, itself a product of carbohydrate metabolism, is dependent on the presence of a co-carboxylase which has recently been identified as the di-phosphoric ester of aneurin, vitamin B₁.¹ In diseases known to be due to a deficiency of vitamin B₁, such as beriberi and peripheral neuritis, pyruvic acid accumulates in the body fluids (blood and spinal fluid). Methods of estimating pyruvic acid² and co-carboxylase^{3,4} in the blood have recently been devised and applied to determinations of these substances in the body fluids of children and adults in order to find out how far the amounts may be influenced by various pathological conditions. Wortis, Goodhart, and Bueding⁵ examined fifty children in the psychiatric division of the Belle Vue Hospital, New York, who had been admitted on account of conduct disorders, behaviour problems, psychoneuroses, and mental deficiency. None of them showed any of the generally accepted pathological signs of vitamin B₁ deficiency, nor were any of them suffering from any febrile or wasting disease. They came from a low economic stratum of the city's society and might therefore be expected to have received somewhat small amounts of vitamin B₁. The amounts of co-carboxylase found in their blood ranged from 4 to 13 μ g., average 7.5 μ g., per 100 c.cm. The findings of Goodhart and Sinclair⁴ in England of 4.5 to 12.0, average 7.0, μ g. per 100 c.cm. for twenty-six adults are very similar to those of the New York findings. Wortis *et al.*⁵ also found 0.71 to 1.21, average 0.96, mg. of pyruvic acid per 100 c.cm. of blood and 0.70 to 1.02, average 0.86, mg. per 100 c.cm. of cerebrospinal fluid in thirty-five children. The corresponding figures found in sixty adults were 0.77 to 1.16, average 0.98, mg. in the blood and 0.42 to 1.21, average 0.815, mg. in the cerebrospinal fluid. These workers do not consider that the total amount of bisulphite-binding substances in blood and cerebrospinal fluid can be taken as an indication of vitamin B₁ deficiency. Schlutz and Knott⁶ consider that a child's blood should contain 10.0 μ g. of co-carboxylase per 100 c.cm. They found that the blood of chronically ill young children (multiple abscesses, severe eczema, prolonged otitis media, and bronchial asthma) contained much less than this. For more acutely ill children the home situation seemed to be a factor determining the co-carboxylase content of the blood. These workers are strongly of the opinion that the level of this factor in the blood may, in general, be maintained equal to that of normal healthy children by careful dieting or by vitamin B₁ therapy.

TREATMENT OF HYPERTENSION BY RENAL EXTRACTS

There is much evidence that the kidney can not only initiate hypertension but can also produce a substance which tends to counteract it. Some observers believe that hypertension depends on the ratio of ischaemic to normal renal tissue. For example, when hypertension is produced in animals by rendering one of the kidneys ischaemic the removal of the other kidney causes a further rise in blood pressure. Experimental injection seems to show that rennin tends to call forth a substance which inhibits its action. Grollman⁷ and Page and his co-workers⁸ have attempted with some success to extract such an inhibitory substance, and the latter have recently published a report of cases of hypertension treated with renal extracts. When first tested on

dogs or rats previously rendered hypertensive, the extracts produced no immediate fall in blood pressure; in fact there was a sharp rise at first, probably due to the presence of rennin. After two to four days' treatment there was a consistent fall which lasted for several days even if treatment was stopped. Renal insufficiency actually improved with the fall in blood pressure and the condition of the animals also improved so long as the extract was given. In one instance the fall in pressure was from 200 to 130 mm. In human beings the results were similar. After two days' treatment five patients with malignant hypertension, who were previously stuporose, were alert and sitting up in bed. All had retinal changes (two were almost blind), and the vision was partially restored with visible improvement in the appearance of the retina. Radiographs and electrocardiograms showed improvement in the cardiac condition, and in some cases the urea clearance increased. Blood pressures fell, for instance, from 240/150 to 180/110, but rose again when treatment was stopped. Two of the patients died (one had a urea clearance of 5%; the other refused further treatment). In the remaining three the improvement was maintained at the time the paper was written. Patients with essential hypertension of the so-called benign type responded similarly. Headache, when present, disappeared and dyspnoea improved. The fall in blood pressure varied in different patients; in one case a pressure of 229/119 fell to 157/78. The amount of kidney necessary to make the extracts was about one kilogramme or rather less per patient per day. Some general and local reactions occurred, such as pain in the back and a sensation of constriction in the chest, with pyrexia in some cases. These became rarer as more purified extracts were used. It is too early to say that the problem of the treatment of hypertension is nearing solution. The work needs confirmation, and the patients' subsequent progress will have to be carefully studied. This work, however, is more encouraging than anything which has been published for a long time on the treatment of hypertension.

IS THE SAFE PERIOD SAFE?

Is the safe period safe? It has been sponsored from Germany and Japan and blessed by Rome, but even this evidence of a tripartite agreement has failed to allay the many fears that still exist among anxious neutrals. Knaus has accumulated relevant data for many years and claims that its analysis supports his belief that there is a period of infertility in the monthly cycle of a woman. The evidence of physiological experimentation which he offered to support his views has been challenged by many workers, but has been approved recently by no less an authority than Reynolds in his book *The Physiology of the Uterus*. Whatever controversy may centre round the question of this experimental work, the fact remains that Knaus produces evidence that cannot be contested of the efficacy of the safe period when applied in practice. From time to time evidence is offered from other quarters to suggest that the term "safe period" is a misnomer, and as more and more conflicting data are published the general practitioner finds it increasingly difficult to advise his patients on this subject. Recently John Pryde,¹ in a contribution to the study of human fertility, recorded data from two cases in which a total of 576 acts of intercourse without contraception had occurred during calculated safe periods with no resultant pregnancy. In each case the first act during a fertile period was followed by gestation. A clinical study of the problem has also been presented by Stephen Fleok, Elizabeth Snedeker, and John Rock.² Their paper was

based on the records of the Rhythm Clinic of the Free Hospital for Women in Brookline, Massachusetts. At this clinic patients are supplied with calendars on which they record the dates of menstruation and coitus. On the assumption that the fertile period extends from the nineteenth day before the earliest likely first day of menstruation until the ninth day before the latest likely first day, each calendar has the days of this theoretical fertile period crossed out a month in advance. Every month immediately menstruation ceases the calendars are returned to the clinic, where they are checked and the safe period for the ensuing month is marked. A preliminary selection is made at the patient's first visit to the clinic to exclude those who would be unsuitable for the practice of this method of contraception, and applicants are rejected if there is gross menstrual irregularity or if pregnancy already exists. The authors analyse the records of 207 patients who were accepted. There were twenty-one unwanted pregnancies in this series, but no fewer than fourteen of these occurred when advice given was not carried out, and one followed a mistake in calculating the safe period and may be classified as a "typist's error." The six remaining pregnancies could not be explained. The patients asserted that instructions had been followed in detail, and it is therefore necessary to admit that there is at least a 3% risk of failure, even if all precautions are taken in the application of the method. The conclusion reached was that the safe-period method constituted a workable form of contraception for a selected group of women, but was not reliable enough to be advocated in those cases in which for medical reasons it was essential that pregnancy be avoided. In view of these findings the doctor may with reason be hesitant in advocating the use of the safe period to those of his patients who wish to avoid pregnancy at all costs. On the other hand, he has ample clinical evidence to support him in advising his patients of the fertile period, of which advantage should be taken when sterility exists for no determined reason.

We much regret to announce the death of Sir Frederic Still, K.C.V.O., M.D., consulting physician for diseases of children at King's College Hospital, and consulting physician to the Hospital for Sick Children, Great Ormond Street. Sir Frederic had been chairman of the Editorial Committee of the *Archives of Disease in Childhood* from the time of its establishment in 1926 by the Council of the British Medical Association. We also record with regret the death of Major-General Sir William Pike, K.C.M.G., D.S.O., F.R.C.S.I., who was D.M.S. of the Fourth Army in 1917.

The second section of the Birthday Honours List, for members of the Services, includes the promotion of Air Marshal Harold Edward Whittingham, Director-General of the R.A.F. Medical Service, to be K.B.E.

The Royal Medico-Psychological Association will hold its one hundredth annual meeting on Thursday, July 17. The business meeting will be held at 11, Chandos Street, W., at 12 noon, and the afternoon session, during which papers will be read on the subject of "Ear, Nose, and Throat Disease in Mental Disorder," will begin at 2 p.m. at the Barnes Hall, Royal Society of Medicine.

The forty-first annual meeting of the Canadian Tuberculosis Association was held in Toronto on June 6 and 7 in conjunction with the annual meeting of the Ontario Laennec Society, and it was followed by a meeting of the American Association of Thoracic Surgeons.

CHEST SURGERY IN WAR

This is one of a short series of articles based on lectures given at the British Postgraduate Medical School, Hammersmith

CLOSED WOUNDS OF THE CHEST, AND THE PHYSICIAN'S PLACE IN A CHEST TEAM*

BY

J. A. NIXON, C.M.G., M.D., F.R.C.P.

Intrathoracic Injuries

We may now pass to a consideration of the intrathoracic injuries pure and simple. The distress caused by an open thorax is usually very great, and until the opening has been closed it is difficult to estimate the extent to which the symptoms are due to injury of the thoracic contents. Auscultation and percussion will add little or nothing to the information obtained by seeing the hole in the chest wall. Active haemorrhage may be visible externally and be recognizable by the colour of the blood, which continues bright and arterial. The leakage of a haemothorax which is not increasing from fresh haemorrhage is usually darker and resembles venous bleeding; moreover, the blood does not clot outside the body as fresh blood does. Injuries to the thoracic duct cause rapid and uncontrollable wasting. With closed thorax the examination of the chest resolves itself into a combination of the ordinary methods (inspection, palpation, percussion, and auscultation) with radiology and radiography.

Inspection.—The presence of surgical emphysema almost always means the presence of either partial or complete pneumothorax. If the heart's apex beat is visible an alteration of its position may depend on the heart's being pushed over by air or fluid, or on its being pulled over by collapsed lung. Visible distension of one side of the chest may depend on air or fluid. An overdistended chest will generally be immobile. The degree of movement in a chest is not, however, always proportionate to the intrathoracic injury. On the one hand there may be, for instance, a considerable amplitude of respiratory movement with a large haemothorax if the lung remains partly expanded; and, on the other hand, a chest which has been struck without material intrathoracic damage may remain immobile for two or three days even though the lung is not collapsed, and even in the absence of haemothorax or pneumothorax. Cases of this kind are seen in which the injured side remains resonant, slightly retracted, without inspiratory or expiratory sounds, but with normal vocal fremitus and normal radiographic appearance. This condition persists for one or two days and recovers completely. In cases of collapsed lung (without haemothorax or pneumothorax) the side may appear greatly retracted, with indrawing of the interspaces on inspiration.

Palpation.—Surgical emphysema is the first sign to be felt for. If extensive it obliterates or distorts every other physical sign except the position of the heart. Displacement of the heart may be determined by palpation. Exocardial friction fremitus may be felt. It does not always indicate haemo-pneumopericardium or pericarditis: sub-sternal surgical emphysema may cause a similar friction fremitus. Fractured ribs or a missile lying under the skin may be discovered by palpation. An ecchymosis on the chest wall should be carefully palpated, as it is often due to a missile which has penetrated as far as the skin

without making its exit. Tactile vocal fremitus is not always diminished and is occasionally increased over haemothorax. It is not even invariably lost over pneumothorax. The value of palpation can scarcely be over-emphasized.

Percussion.—Percussion is apt to be misleading when the chest has been injured. The resonance of the normal chest depends to some extent on the tension of the chest wall, in the same way as the resonance of a drum depends on the tension of the drum-head. If the chest wall becomes abnormally lax (as when ribs are extensively smashed) the resonance and the pitch of the percussion note are thereby altered. Surgical emphysema will yield a resonant note even over a large haemothorax. Resonance may be impaired over a collapsed lung even if there is no haemothorax. The level of dullness does not indicate the size of a haemothorax. Alteration in the position of the mediastinum may be detected by percussing out the anterior limits of resonance of the uninjured lung. The position or size of the cardiac dullness may be found changed. The liver dullness or stomach resonance is sometimes found to rise unduly high in chest wounds owing to relaxation or paralysis of an apparently uninjured diaphragm. This may mean that the diaphragm is paralysed or that the lung above it is collapsed. Particular attention should be paid to percussion of the base of the opposite (and apparently uninjured) lung. Abnormal dullness of this base may be due to an abnormally high diaphragm, to consolidation, collapse, or compression of the lung, or to a haemothorax. A missile may have passed through both lungs. The diaphragm may be pushed up by subphrenic injuries or by tympanites and cause abnormal dullness at the pulmonary base or bases.

Auscultation.—The positive sign of good air entry with normal vesicular breathing is the most valuable of all auscultatory sounds. It is evidence that the lung in that area is expanding. Absent and altered breath sounds are less reliable. Breath sounds may be diminished or totally absent in haemothorax and pneumothorax; they may be equally absent in any case in which the lung is not expanding—for example, when a bronchus is blocked or when the respiratory movements are too feeble (as in shock) to produce any audible sound. Altered breath sounds do not follow the same general rules in injuries as in diseases of the lungs. Bronchial breathing is not uncommon over haemothorax, whilst it may be absent in haematoma of the lung if the haematoma is superficial and wide in extent. Bronchial or amphoric breathing is often heard over pneumothorax even when closed. The coin-sound is sometimes absent even in a large pneumothorax.

Mucous and Crepitant Rales.—It is very difficult to assign particular values to mucous rales and crepitations in the same way as has hitherto been customary in disease. When it is remembered that, in the majority of cases where the lung has been struck, three changes almost invariably occur which are capable of producing mucous or crepitant rales, the difficulties of exactly interpreting these physical signs will be appreciated. The three constant changes are collapse of air vesicles, haemorrhage into the alveoli and bronchioles, and haematoma of the lung. Whatever other accidents may have occurred these three may be confidently assumed to be present when a missile has struck the chest with enough force to penetrate

its wall. Mucous rales will give practically no information of diagnostic value. Crepitations are occasionally useful, particularly in two conditions. In collapse of the lung (either homolateral or contralateral) widespread coarse dry crackling is a valuable physical sign. In compression of the opposite lung by a large haemothorax or pneumothorax on the injured side fine crepitations are often heard over the base of the compressed lung. On the second or third day (and at any later time) the appearance of crepitations where none were previously heard may indicate the occurrence of pneumonia or bronchopneumonia, or that extremely rare condition gas gangrene of the pulmonary tissue.

Friction Sounds.—Pleural friction must be carefully watched for. It is often the first sign of intrathoracic infection. But a small haemothorax almost always at an early stage produces friction which is of no great moment. Pericardial friction is not uncommon, but pericarditis is not necessarily a fatal or even a serious complication of gunshot wounds of the chest. A heart beating in surgical emphysema of the substernal tissues may give rise to a friction sound indistinguishable from pericarditis or to a remarkable churning sound mistakable for haemo-pneumopericardium. An adjacent pneumothorax will give to the normal heart sound an exaggerated resonance or reverberation, and if friction is present either from pericarditis or surgical emphysema, or from haemo-pneumopericardium, the noises which may result are astonishing, although with experience they become unmistakable. As a rule the exocardial friction sounds which appear immediately after wounding are due to surgical emphysema, and are very loud and coarse. They begin faintly over a limited area and spread gradually with increasing loudness. Hernia of the stomach or intestines may cause gurgling sounds to be heard in the chest, but these sounds are not diagnostic of a lacerated diaphragm. Intestinal gurgling is sometimes transmitted very distinctly through a pneumothorax when the diaphragm is intact, and it is also heard when the diaphragm is raised abnormally high. It is very difficult to interpret changes in the heart sounds and rhythm correctly. Bruits which are mistaken for endocardial murmurs are produced by displacement of the mediastinum with dislocation or torsion of the heart and great vessels. Irregularities in rhythm may be similarly caused. Speaking generally, a heart which has been hit, with or without penetration, takes on a rapid and irregular action, especially if struck on the posterior aspect or near the auriculo-ventricular junction. I have, however, seen in one case a shrapnel ball lodged in the ventricular muscle near the apex, and in another a fistulous opening through the chest wall into the right auricle, yet in neither was there any interference with the heart's action. But as a rule true delirium cordis indicates that the heart has been struck by the missile. Physical signs suggesting involvement of the pericardium or heart do not constitute a contraindication to operation. They are exceedingly fallacious.

Succession Splash.—It may be possible to elicit this sign in haemo-pneumothorax. It is never justifiable to attempt to do so in the early stages, and with x rays at hand it is never necessary.

Metallic Tinkling.—I thought that I had never met with this sign in gunshot wounds of the chest, but recently I found a note of it in one of my cases at Heilly (in 1916).

Voice Sounds.—Modifications of vocal resonance are apt to be misleading. The most constant and reliable sign is aegophony, which I have not met with except when there was fluid in the chest. It is usually best heard at or near the upper level of the fluid, and may be localized to a very restricted area there. Diminished vocal resonance

does not always accompany even a large haemothorax it may be considerably increased. Occasionally the vocal resonance is increased without any obvious intrathoracic change even on x-ray examination. I do not know what is the explanation of this sign occurring in a chest which has been hit or penetrated. I have often met with it in the first few hours, and have not been able to attach any importance or diagnostic significance to it. Possibly it is due to a partial deflation of the lung that is not sufficient to produce the physical signs of collapse. In pneumothorax the voice sounds and the cough may acquire a characteristic metallic ring. This metallic ring is also sometimes heard with the inspiratory souffle in a closed pneumothorax, and indicates that a large opening communicates with the pneumothorax from the bronchus.

Auscultation is made very difficult when surgical emphysema is present. If the surgical emphysema is considerable and obvious, it will be recognized at once that auscultation can be of little assistance. Often, however, the emphysema is not evident, and the auscultatory sounds become very puzzling, particularly when the surgical emphysema is mediastinal, substernal, or subpleural, and does not extend to the subcutaneous tissues. Under all circumstances auscultation should reveal the approximate position of the heart, and this is a point which requires to be determined in every case of gunshot wound of the chest.

Value of Radiography

It is impossible to treat chest wounds adequately without radiographs. From the time a case comes within reach of surgical assistance to the time the patient is finally discharged as cured, and even long after if untoward sequelae are suspected, radiographs are constantly required. At the outset it is only with radiographs that the probable track of a missile and its position, if retained, can be ascertained. The position of the heart and diaphragm, their movements, damage to the lung, collapse of the lung, haemothorax, and pneumothorax can only be accurately determined by radiographs interpreted in conjunction with physical signs. Radiography alone is insufficient; the cases must also be radioscopically examined and the parts be seen in movement with the fluoroscopic screen, in a sitting-up position if possible. It must be remembered that pieces of clothing can never, and fragments of bone only rarely, be revealed by radiographs.

Some Other Considerations

One of the most reliable signs of a haemothorax becoming septic is an increased respiration rate and even apparent dyspnoea without any corresponding change in physical signs or increase in the amount of fluid. Air in the pleural cavity plays little or no part in preventing a collapsed lung from expanding unless there is a valve pneumothorax constantly pumping air into the pleural cavity. The rapidity with which a collapsed lung can re-expand if free from adhesions is not generally known. I had accidental proof of this during the last war. A patient on whom complete thoracotomy had been performed was by mistake radiographed within two hours of his operation. The lung, which had been fully collapsed at the operation, was found both by screening and by a photographic plate to be almost completely re-expanded. The thoracic wound had been hermetically closed and covered with glue.

"Pleural shock" is a terror to some minds. But the pleura is not a delicately sensitive membrane. Opening the pleural cavity and handling the lung can be done with impunity if care is exercised not to allow displacement of the mediastinum and contents.

If the mediastinal contents are gently held in place with tenaculum forceps a patient under local anaesthesia experiences very little discomfort and no shock when the thorax is opened, the cavity explored with the hand, and the lung even "delivered" outside the chest for examination and repair. If, however, the heart is allowed to swing out of position grave shock may occur immediately. I have seen a patient whose heart was pinned in position by a small fragment of metal which attached the pericardium to the diaphragm almost die on the operating table when the heart was released and allowed to swing to the opposite side of the chest, although a total pneumothorax had caused him little discomfort either at the time of wounding or after the thorax had been widely opened at the beginning of the operation. It is very striking to find how little is the distress caused by sudden pneumothorax when the heart is retained in position by old adhesions. In 1921 I saw an example of this in a soldier who was wounded in 1915; his pneumothorax, dating from that time, was discovered only by accident in 1921. His heart was held in position by adhesions which were probably present before he was wounded. In cases showing extreme distress relief is instantaneous when, after opening the chest for thoracotomy, the heart is gently drawn back into position.

The heart is a strange organ. It appears to resent blows on its posterior aspect more than on the anterior; it also resents anything like torsion during an operation. If the heart impinges on a foreign body during its beating the rhythm and rate may be totally disordered even when the heart itself is quite uninjured. Never diagnose haemopericardium until you have seen the pericardium exposed either during life or after death.

Breathing exercises are apt to be overvalued. With a well-cleaned pleural cavity a lung expands perfectly without exercises. The toilet of the pleura is what matters. Lockwood and I eventually abandoned exercises altogether, as they only fatigued the patient uselessly. Mr. Tudor Edwards in his memorandum E.M.S. Gen./326 says he is doubtful if blowing exercises have the slightest value in the re-expansion of a lung bound down by pleural adhesions. I have often demonstrated what happens radioscopically. The good lung overdistends, the mediastinum bends convexly into the damaged side, and the harder the patient blows the greater is the mediastinal displacement.

Official History of the War. Medical Services: Surgery. Vol. 1, H.M.S.O., London.

The thirty-fourth annual medical report of the King Edward VII Sanatorium, Midhurst, is almost entirely statistical. It analyses the admissions and discharges (142 and 172 respectively) of the past year and also the after-history of the Midhurst cases since 1906. Of the 149 patients discharged in the first year of the sanatorium's existence, 27 were still alive in 1940. The more astonishing thing is how few are lost sight of—something under 5%. The treatments given are also analysed; thus during the last fifteen years artificial pneumothorax has been attempted in 303 cases, and has been successful in 240. Of these 240 patients, some of them dating back to 1925, 182 (or 76%) are known to be still living. Eighteen patients out of 15 severe cases and 23 less severe in which thoracoplasty was done were known to be working or fit for work, 6 to be well though not working, and 5 to be keeping in fair health. On the outbreak of the war, half the sanatorium was taken over by the Ministry of Health for the treatment of surgical chest cases among the officers of the three Services. These cases are not discussed in the present report, but it is proposed at the end of hostilities, or earlier if the number of cases requires it, to give a full analysis of the cases treated.

THE PREPARATION AND COOKING OF GREEN VEGETABLES

The following note on the preservation of the vitamins and salts in the processes of preparing green vegetables for the table has been drawn up by the Medical Research Council's Accessory Food Factors Committee.

Conservation of Vitamins

Vitamins are lost or destroyed in the preparation and cooking of greenstuffs by many of the methods now in common use. As it is of special importance at the present time to secure the maximum nutritive value from all the foods available, it is desirable to employ methods of preparation and cooking of foodstuffs which conserve their nutrients to the utmost.

The following generalizations summarize our knowledge of the behaviour in greenstuffs of the vitamins most likely to be affected in the course of preparing green vegetables for the table. Some simple rules based on these generalizations are given and cooking methods for greenstuffs are recommended.

Fat-soluble vitamin A is unlikely to suffer damage; water-soluble vitamins B and C are the most likely to be lost on preparation and cooking. This is so for the following reasons:

- (i) Because they are water-soluble, they are dissolved out by soaking or cooking water, they also run out in the watery juice.
- (ii) Raw vegetables contain enzymes which are active in destroying the vitamins, particularly if the raw foodstuff is left lying about after being bruised or cut up. These substances which destroy the vitamins become more active as the temperature rises during cooking up to a point at which they themselves are destroyed. This point of destruction is only a few degrees below boiling temperature.
- (iii) The water-soluble vitamins are themselves also destroyed by heat to an extent which depends on the length and severity of the heating.
- (iv) The water-soluble vitamins are found to diminish in amount in foods left standing after they are cooked.
- (v) Salt or sugar added to vegetables before cooking lessens the amount of destruction under conditions described in (iii) and (iv) above.
- (vi) Vitamins B and C are more stable in the presence of acid, which is sometimes added as vinegar. The addition of alkali (carbonate or bicarbonate of soda) will, on the other hand, hasten the destruction of the vitamins.

Practical Rules for treating Green Vegetables

- (1) Obtain as fresh as possible.
- (2) Keep in a cool damp place in order to reduce wilting.
- (3) Take precautions to avoid damage due to crushing or bruising during transport or handling.
- (4) If vegetables are soaked use salt water (two teaspoonfuls to one pint).
- (5) If vegetables are to be shredded or finely chopped for salads, prepare immediately before serving.
- (6) Use the smallest possible amount of water for cooking.
- (7) Have water boiling before adding vegetables.
- (8) Add salt to water before adding vegetables.
- (9) Add vegetables gradually or in small amounts at a time, in order to prevent water going off the boil.
- (10) Cook vegetables no longer than is necessary to render them tender.
- (11) Plan cooking arrangements so that vegetables are dished up and served immediately after they are cooked. On no account allow to stand for a long time on a hotplate.
- (12) If there is water left after cooking, drain off and use in the preparation of soups and gravies; alternatively, if successive batches are being cooked on the same day, use the same water again, adding more if necessary.

Methods resulting in Least Loss of Vitamin C

Method 1.—Boil for the shortest time in a small quantity of boiling salted water. Use water left over for boiling other batches and for addition to soups and gravies.

Method II.—Slice the fresh vegetables into ribbons about 2 to 3 inches long by 3/4 inch wide and cook briskly for half to one minute in a small quantity of hot oil or dripping to which salt has been added (two teaspoonsful of oil and half teaspoonful salt to an average-sized cabbage). Add a small quantity of boiling water (half to one cupful for above) and stew for about ten minutes in a closed container. Keep the lid on so that no steam escapes. When the vegetables are cooked only a very little water should be left. This method is used throughout the Far East and India. In Europe the nearest approach to it is the French method of "casserole" or "conservative" cooking, by which the vegetables are placed in a closed fireproof dish with a little water and fat and cooked in the oven or over a low flame for 15 to 25 minutes.

In hay-box cookery vitamin C is destroyed, so that this method should not generally be used for cooking green vegetables, which are particularly valuable in the diet for their vitamin C content.

Steaming of vegetables even with the best equipment is not as satisfactory as the methods described above.

Conservation of Salts

If the precautions described above are carefully taken, it can be relied on that effective conservation of the valuable salts present in green vegetables will also be secured.

INVALIDS, AND BREAD FORTIFIED WITH CALCIUM

The following statement concerning the effect upon invalids of bread made from flour "fortified" by the addition of calcium salts has been issued by the Medical Research Council:

The exigencies of the present situation have forced upon the people of the country a diet which requires, if health is to be maintained, the addition of a supplement of calcium salts. The need for this supplement is brought about in two main ways: (1) the wartime diet tends to be deficient in available calcium, especially since restrictions have been imposed upon the sale of milk and eggs; (2) the high content of cereal foods in the diet increases the amount of calcium it is necessary to ingest: this is partly because most cereals are deficient in calcium but also because the presence of phytic acid in cereals often prevents the body from making use of the calcium they contain. The Ministry of Food has asked the Food Rationing (Special Diets) Advisory Committee whether the addition of small supplements of calcium salts to flour would be in any way deleterious to invalids. In reply the committee expressed the opinion that "there is neither medical nor scientific evidence that the consumption of bread made from flour fortified by the addition of appropriate quantities of calcium salts is harmful to patients suffering from any type of disease." This opinion was based on the following considerations.

It has been proposed by the Accessory Food Factors Committee of the Lister Institute and of the Medical Research Council that 14 oz. of calcium carbonate be added to each 280 lb. of 85% extracted flour and 7 oz. of calcium carbonate to each 280 lb. of white flour. Expressing these quantities in other terms, it can be said that 1 lb. of the "fortified" 85% extracted flour and 2 lb. of the "fortified" white flour contain slightly less calcium than 1 pint of fresh milk. There can therefore be no objection to the use of this fortified flour on the grounds that it will result in the consumption by invalids of harmful amounts of calcium. It is, however, necessary to dispel a current misconception with regard to the qualitative aspect of this fortification. It has been suggested that the consumption of fortified flour might have a deleterious effect upon certain invalids, not because of the increased calcium content, but because the calcium added to it is in a form—the carbonate of calcium—different from that which exists naturally in food and that this carbonate of calcium is harmful.

This criticism appears to be ill founded. There is direct evidence obtained on human beings that the calcium of calcium carbonate is as available to the body as that of calcium phosphate. In an easily assimilable food, such as milk, calcium is in the form of a combination with a phosphoric acid, a common normal component of animal tissues; in calcium carbonate, calcium is also present as the salt of an acid of widespread occurrence in living tissues. In both cases the calcium is split off from the acid during the process of digestion and is absorbed into the body in the same form in each case.

A CORPS SCHOOL FOR THE R.A.M.C.

[FROM A CORRESPONDENT]

For intensiveness it would be hard to beat a week's course which an enthusiastic class from No. 2 Corps R.A.M.C. has recently undertaken in a university town. Thanks to the co-operation of one of the colleges, about 30 R.A.M.C. officers and N.C.O.s have been accommodated in its rooms, the undergraduates being down for the vacation. It was never pretended that more could be done in a week's course than open up and draw attention to a number of subjects which officers should study.

This is not a question of medical subjects pure and simple. The trained R.A.M.C. officer is much more than a medical man in khaki, his patients the men in the Army; he is in his degree a military expert, with a sufficient knowledge of modern methods of fighting, the use of different types of weapons, the technique of supply and transport, and a hundred other matters to make him a well-adapted unit in the many-sided organization of which he is a part. He should be able to read maps, should be trained in drill, should have acquired a soldierly carriage and demeanour, and should have a note of authority in his voice, without which he cannot expect to command obedience, especially when circumstances are trying and danger is imminent.

Therefore, although there were lectures in this course on such subjects as surgery in the field, wound shock, and sanitation, there were lectures also bearing the titles "Signals," "The Armoured Division," "Administration," "Security," "Supplies." Such themes as messing and cooking and office routine were not neglected.

Each of the six mornings of the course began with a short spell of physical drill under the leadership of an instructor. The rest of the morning was given up to four lectures, each lasting some forty minutes, with opportunities for questions at the end. These were given by R.A.M.C. officers of experience and staff officers who had obviously taken great pains to prepare their material. After lunch in the college hall the class had an hour of squad drill, stretcher work, or Thomas's splint drill; then came two more lectures, and after tea the class met in syndicates to discuss problems set by the D.D.M.S. of the Corps in an indoor "tactical exercise without troops." Then mess in hall, and still another lecture, perhaps on a wider or more "popular" subject.

A Specimen Day in the Course

Take a specimen day—the Thursday of the course. After physical training the four morning lectures are on "Fire Signals," by a Fire Officer; "Military Law," by the Commandant; "Routes and Convoys," by the M.A.C. Officer; and "The Field Ambulance," by the A.D.M.S. of the Division. In the afternoon squad drill and triangular bandages, and then two lectures, one of them on "Flies and Vermin," by the officer commanding the Field Hygiene Section. In the evening, instead of a popular lecture, solutions are given by the D.D.M.S. to the problems set in the tactical exercises. This is one of the most instructive events of the week, and a vivid picture is built up of the details with which medical officers should be familiar in battle. Medical tactics are discussed and points emphasized by question and answer in a two-hour session.

This Corps School is the direct descendant of the No. 6 Corps School which was started in 1916 by Major-General Sir Harry Thompson and continued in the following year as the First Army R.A.M.C. School of Instruction (B.E.F.). The syllabus is much the same and the general policy identical. The chief instructor and late Commandant of the old Army School is now D.D.M.S. of the Corps. The Commandant is an R.A.M.C. officer with recent war experience, and the Adjutant did good work as a regimental medical officer in Flanders last year. During the week's course these officers were accessible at all times to answer questions and explain any points that had arisen out of the day's lectures, and this was perhaps even more useful than the set programme.

On the last morning, after a lecture on physical medicine by the Commandant, the course ended with a demonstration of the carrying of casualties and a visit from the Corps Commander, whose personal interest in the work of the R.A.M.C. has been at all times most stimulating. Later arrangements included a class lasting one week for N.C.O.s, and a short study week for senior R.A.M.C. officers.

AWARDS FOR GALLANTRY IN CIVIL DEFENCE

The award of the George Medal to Dr. Hannah Billig, Stepney, to Dr. Bernard Doyle, and to Mr. S. Woolfson, District A.R.P. Warden, Stepney, and to Dr. Allison Jean McNairn, assistant medical officer, City General Hospital, Plymouth, is announced in a *Supplement* to the *London Gazette* dated June 27. The announcements read as follows:

Dr. BILLIG: "During an air raid Dr. Billig, although herself injured, left shelter to attend to casualties in the street. Bombs dropped within twenty yards of her, but for four hours she continued to give treatment to the injured. She showed great bravery and attention to duty, regardless of her personal safety and injuries."

Dr. DOYLE and Mr. WOOLFSON: "During a severe air raid a large building was hit and caught fire. Dr. Doyle and District Warden Woolfson entered that part of the building which was alight and wrecked and found two men trapped. Two high-explosive bombs which rocked the blazing building dropped within twenty yards of the rescuers, but they continued their rescue work and both victims were removed to safety. More high-explosive bombs fell nearby and two men of the rescue party were buried. One of these men was quickly removed, but the other was pinned down by half a ton of masonry. Dr. Doyle was again called to give treatment, and whilst so doing more bombs were dropped, but in spite of this Dr. Doyle stayed with the casualty until he was removed to hospital. Woolfson remained at the scene of the incident the whole of the time aiding the rescue work, and did not leave until all casualties had been removed from the building. Both men showed great courage in very dangerous circumstances."

Dr. McNAIRN: "When the hospital was hit Dr. McNairn was buried to the neck in debris. She was extricated, and despite shock and injuries, assisted in the rescue work and gave medical assistance to injured patients and air-raid casualties admitted to the hospital. She would not have treatment for her own injuries until all other cases were being cared for, but despite severe pain continued to give aid."

NATIONAL BABY WEEK

The twenty-fifth National Baby Week opened on Tuesday, July 1, and messages of encouragement have been received by the National Baby Welfare Council from its Patron, Queen Mary, from the Minister of Health, and from Sir Wilson Jameson, Chief Medical Officer to the Ministry of Health. The function of the Council (whose offices are at 29, Gordon Square, W.C.1) is to educate public opinion on matters connected with the welfare of mothers, babies, and little children. Queen Mary writes: "I am sorry that the jubilee celebration of the twenty-fifth National Baby Week should have fallen in time of war. Nevertheless I am glad to have this opportunity of paying a warm tribute to what has been achieved by the National Baby Welfare Council during the past 25 years. I know that the Council are now doing their utmost in helping to solve the many new and urgent problems in the care and well-being of mothers and small children arising out of the difficulties and tragedies of wartime conditions. To one and all who are striving in this vital cause I send my congratulations upon this jubilee anniversary and my best wishes for continued success in the years to come." The July, 1941, issue of *Mother and Child*, official organ of the National Council for Maternity and Child Welfare (Aldwych House, Aldwych, W.C.2), is a special Baby Week Number. It includes a commemorative editorial by Dr. Eric Pritchard, chairman of the executive committee 1917-39 (who also writes on milk dilutions and deficiency symptoms), a paper by Dr. Leslie Housden on the relation of mothercraft teaching to family allowances, and a record of progress in the campaign for immunization of children against diphtheria.

There will be no more "white bread" available in the Union of South Africa for a long time. The Union has had to import so-called "hard wheat" from Canada to make up for the deficiency in the grade of home-produced wheat for bread-making, and the wheat cannot now be imported owing to the requirements of shipping for war purposes. The Government has therefore decided to introduce a standard loaf in which only whole wheat is used. Dietitians maintain that this bread is more nutritious than white bread or the brown variety made of unsifted flour.

Local News

ENGLAND AND WALES

Epsom College

The President, Lord Leverhulme, took the chair at the eighty-eighth annual general meeting of Epsom College, held on June 20, at 49, Bedford Square, London, W.C. In moving the adoption of the Council's report he congratulated the headmaster and his staff, the secretary and bursar and those associated with him, on the way in which the work of the school and the Foundation had been maintained. He pointed out that some public schools had necessarily had to be evacuated to quieter parts of the country, and thought that the present generation of Epsomians in passing through the school would count themselves fortunate in future years that their public-school lives were passed amid surroundings familiar to all old Epsomians. The President expressed the Governors' deep gratitude to Dr. John Fawcett for his services during the past six years as treasurer. In proposing as his successor Surgeon Vice-Admiral Sir Reginald Bond, he said that it was fitting that the College should have a distinguished member of the Senior Service in this office now. The Governors unanimously adopted the Council's Report and received the announcement of foundation scholarships and pensions awarded by the conjoint committee which met in May last.

IRELAND

Medical Research Council of Ireland

The Medical Research Council of Ireland, of which Prof. R. P. Farnan is chairman and Prof. J. W. Bigger honorary secretary, states in its fourth annual report that during 1940 the policy was followed of continuing as far as seemed wise and feasible the support of workers already appointed, and not many fresh appointments were made. Such a policy, of course, risks discouraging research-workers who might under favourable conditions be assisted and developed, but as experience in research is gained only slowly and with difficulty it is considered that it would be unwise to sacrifice what has already been achieved. The necessity for encouraging research workers is emphasized. In a country like Ireland the reputation of the medical profession outside its boundaries depends very largely on the research work done by its members, and the value of an improved reputation of the Irish medical profession alike to the progress of the State and to the Irish doctors who have to seek work abroad is self-evident. The hope is expressed that when the Council again approaches the Minister for Local Government and Public Health (as it did in 1938) it will be found that the Government and the community realize the importance and worth of its activities, and that it will be possible for the Minister to place an adequate capital sum at its disposal, or at least a larger income and for a longer term of years than the £5,000 a year for five years which is at present granted. New grants were made during 1940 to three whole-time and two part-time workers, as well as five grants-in-aid, and grants were renewed to five whole-time and four part-time workers. Special attention is drawn to the work done by one grantee, Dr. R. A. Q. O'Meara, on diphtheria antitoxin. This work was initiated on account of the high death rate from diphtheria in Dublin. From Dr. O'Meara's work it was concluded that diphtheria toxin has two components, which he has named substances A and B, and that the type of toxin responsible for hypertoxic diphtheria is that in which a high proportion of substance B relative to substance A is found. During 1940 a limited amount of antitoxin rich in antibody to substance B became available for clinical trial at Cork Street Fever Hospital, Dublin, and of sixteen cases of infection with the *gravis* type of organism so treated, the cases being chosen because of their extreme severity, only one died. The dose of this antitoxin found to be effective clinically is only from one-third to one-eighth that of a commercial antitoxin.

Belfast Tuberculosis Scheme

It was announced on June 16 by the Ministry of Home Affairs for Northern Ireland that the Belfast City Council had been relieved of its powers under the Tuberculosis Pre-

vention (Ireland) Act, 1908; that its Tuberculosis Committee had been dissolved; and that two commissioners had been appointed to take control. These steps followed an inquiry by Mr. J. Dunlop and Dr. E. Armstrong into the administration of Whiteabbey Sanatorium and Graymount School. The Ministry found that the medical superintendent officer of health, Dr. C. S. Thomson, was deserving of censure; that the city treasurer, the steward clerk, and Sister S. J. W. Houston were deserving of severe censure; that Dr. P. S. Walker, the medical superintendent, and Miss J. M. Lamb, the matron, should be retired from their respective offices; and that the official stocktakers should not be re-employed. As a result of the action of the Ministry in dissolving the Tuberculosis Committee of the City Council, the Belfast Corporation on June 20 appointed six members to investigate the various municipal departments, and the Lord Mayor announced that Dr. Walker, whose retirement had been ordered by the Ministry, had resigned his post owing to ill-health.

Correspondence

Crush Injuries

Sir.—In the article on "Crush Injury with Impairment of Renal Function" (March 22, p. 427), Dr. D. Beall and I stated that we had been unable to find any account of similar cases in the literature. This surprised us, since such injuries are not uncommon in any war conducted along modern lines; in certain civil occupations (e.g. mining) similar damage seems also possible. We have since discovered references to it by a more thorough search of the German literature.

The first description is that of Colmers (1909), who described among 83 casualties from the Messina earthquake 19 suffering from "acute pressure necrosis." Unfortunately, the German expedition arrived on the scene fourteen days after the accident, when all the acute cases had died, and in only one case is there a history of bloody urine and oliguria.

Then, in 1916, Frankenthal described three soldiers who had been buried and showed oedema, bloody urine, and, post mortem, ischaemic muscle necrosis. Little attention was paid, however, to the kidneys. Other pathologists then described similar material, many in journals now inaccessible or in "inaugural dissertations." Among these, Hackradt (1917) from Borst's laboratory described tissue from a nine-hour burial with oedema of the leg, and blisters, and bloody urine containing albumin and casts, the patient dying on the fifth day. Necropsy showed muscle necrosis and tubular degeneration in the kidneys with blood casts. Bredauer later (1920), from the same laboratory, described three further cases.

It was left to Minami in 1923 to summarize the chaotic literature and to investigate more completely material from three cases that had been already briefly described by Lewin (1919) from Pick's laboratory. His description, though incomplete, tallies exactly with our own—e.g., Case II, buried by a grenade explosion for an unknown time, on the second day showed a painful swelling of the left thigh; on the fourth day scanty bloody urine and tenderness in the kidney region; on the fifth day 200 c.c.m. of urine only, less pigmented, was found; and on the sixth day, when death occurred, the urine was still scanty (but now yellow) and contained red cells and hyaline casts. Necropsy showed grey muscle necrosis and oedema of the lungs. The kidney showed normal glomeruli, degeneration of the convoluted tubules, and pigmented masses and ribbons in the collecting tubules and in Henle's loops. Minami also pointed to the analogy with paralytic myohaemoglobinuria of horses, intending, if he could obtain fresh material, to identify the pigment spectroscopically.

By the end of the last war the syndrome was well recognized by Germans, and included in the textbooks of war surgery; in Great Britain, however, it appears to have been both unrecognized and undescribed; nor have I discovered any reference to the German findings. In six of the standard textbooks on war surgery published here and in the U.S.A. there is no mention of it, nor is there in the (yet) few books on that subject published here recently.

Examination of the reasons for this gap in our medical preparedness is almost as important as the finding thereof.

First, while we were not, as the Germans were, fighting on fronts contiguous with our own system of hospitals, yet we

had an efficient pathological service working in France. This developed most highly, however, the bacteriological aspects the enemy, steeped in the Teutonic tradition of morbid anatomy, not only had his crushed and buried patients dying on German-occupied soil instead of at a French base or in mid-Channel, but had the energy to investigate such material. We should be able to learn a great deal from the systematic examination of such traumatic deaths which, until the war had tended towards the perfunctory. Necropsy should be done on air-raid victims whenever possible.

Secondly, the surgeon under wartime conditions is often too busy to give detailed consideration to anything beyond what is absolutely necessary to the well-being of the patient. This is where co-operation between surgeons, physicians and research workers becomes of the utmost importance. Clinical, chemical, and pathological observations adequate enough to make any rational deductions regarding treatment are in many of these conditions far beyond the capabilities of any single, even full-time, worker. The advantages of group research are thus obvious.

Finally, German medicine can never be entirely ignored by us without loss, even though, since the advent of Nazism, its general standard has been in rapid decline.—I am, etc.,

Sulphadiazine and Sulphanil-guanidine against Gas Gangrene

Sir.—Some months ago (*Journal*, 1941, 1, 263) you kindly published a paper by myself describing experiments on the use of sulphonamide compounds to prevent infections by gas-gangrene organisms in experimental wounds of guinea-pigs. This work showed that the local application of these compounds would prevent fatal infection by *Cl. welchii* or *Cl. septicum* in a large proportion of cases; of the three main sulphonamide compounds now in use, sulphanilamide, sulphapyridine, and sulphathiazole, the last named was the most effective. Since this paper was written, two new compounds have been introduced in America—namely, sulphanil-guanidine and sulphadiazine. An investigation has therefore been made to discover whether either of these exerted any greater effect than the three just mentioned. The technique was identical with that previously used. With *Cl. welchii*, six experiments were made using five different strains; generally the infecting dose of organisms was greater than 1,000 M.L.D. All the controls died, mostly in the first twenty-four hours. In the group treated with sulphathiazole, 26 out of 36 (i.e., 72%) survived for more than ten days; in the group with sulphadiazine 13 out of 30 (i.e., 43%) survived; in the group with sulphanil-guanidine 14 out of 33 (i.e., 42%) survived. The virulence of the infection varied a good deal from one experiment to another, so that these totals require a little qualification.

Briefly, in all the experiments the guinea-pigs treated with sulphanil-guanidine were definitely worse than those with sulphathiazole as regards both survival rate and clinical condition. Five experiments were made with sulphadiazine; in three experiments sulphadiazine appeared as effective as sulphathiazole, but never more effective, while in two experiments it was markedly inferior. With *Cl. septicum* two experiments were made, one with over 10,000 M.L.D. and one with less than 1,000 M.L.D. Sulphadiazine appeared to be about as effective as sulphathiazole, while sulphanil-guanidine was inferior on both occasions. From these experiments it is concluded that sulphanil-guanidine is definitely inferior to sulphathiazole in protecting animals against *Cl. welchii* or *Cl. septicum*, while sulphadiazine is no better than sulphathiazole and is probably inferior. This work provided no evidence that it would be advantageous to substitute either of these compounds for sulphathiazole as a local application to wounds.

As regards the rapidity of absorption of these two compounds, sulphanil-guanidine, which is fairly soluble, seemed to be removed from the wound quickly and no remains were macroscopically visible in the wounds of guinea-pigs which died after one to two days; this finding is of interesting contrast with its reputed slow absorption from the bowel, which is

the basis of its use in bacillary dysentery. Sulphadiazine, which is less soluble than sulphathiazole, appeared to be absorbed slowly, and when the wounds were reopened on the third day considerable quantities of the compound were always discovered.—I am, etc.,

Unabsorbable Suture Materials

SIR,—I have been greatly interested in the recent correspondence in the *Journal* on the subject of unabsorbable sutures. For the past twenty years I have used nothing but linen thread (No. 60) for ligatures in the operation of radical mastectomy and have seen no ill effects result. Formerly I used thread exclusively for ligatures in thyroid operations, but an occasional subcutaneous sinus occurred. I therefore substituted fine catgut for ligation of bleeding points superficial to the deep fascia and continued with thread for the deeper ligatures with complete success.

For clean wounds in safe areas thread ligatures have the following advantages over catgut: (1) Thread can be boiled and its sterility is therefore guaranteed. Unfortunately an occasional "batch" of catgut appears to be far from sterile. (2) The tensile strength of thread is comparatively constant while that of catgut varies. With a little experience it is easy to sense how much strain thread will stand and, as a result, ligatures are unlikely to snap. (3) The surface of thread is rough while catgut is smooth and slippery. Consequently thread knots hold more effectively and "slipping" of a properly applied thread ligature is practically impossible. (4) Economy. In operations where a hundred or more ligatures are commonly necessary the cost of thread as compared with catgut is measured in terms of pence instead of pounds.—I am, etc.,

London, W.1, June 26.

Treatment of Osteomyelitis

SIR,—Mr. H. J. McCurrich's letter (June 14, p. 906) regarding chronic osteomyelitis following war wounds raises several important points in the treatment of this surgical problem.

Once the condition is established in certain situations, one of which he mentions, the problem of treatment is indeed great. Some cases following the last war had infection eradicated by wide guttering operations, notably in the hands of the late Naughton Dunn, but, as Mr. McCurrich points out, it is not uncommon for a man to have a discharging sinus for twenty-five years. Having seen many cases of this type I am firmly convinced that, to improve results, we must concern ourselves more with prevention than cure, by recognizing in the initial stage those wounds which are likely to become the seat of a chronic infection. If this is done, more radical methods can be employed in the primary stage of treatment than would be possible some years later.

As an instance I cite the case of a man wounded in the shoulder in the evacuation from Dunkirk. The head of the humerus and part of the glenoid were shattered and numerous metallic fragments scattered in the region. When he reached me the wound was almost healed and surgical intervention was not indicated. Radiographs now show a number of metallic fragments embedded in a shapeless mass of bone at the upper end of the humerus. I do not think that the function of the arm would have been any worse had all these bony and metallic fragments been cleaned out in the first instance, but I do know from previous experience that a chronic infection is likely to supervene in later years, when it will be impossible to do a radical operation short of a fore-quarter amputation.

The upper and lower ends of the femur are notorious for their ability to hold infection in spite of all treatment, and the answer to Mr. McCurrich's question regarding amputation is that each case must be judged on its merits, and amputation performed before it becomes a life-saving operation. Many patients continue for years with a small dressing which is much less of a disability than an artificial limb.

The suggestion of a centre or colony for these patients is surely already met in the Ministry of Pensions Hospitals, where a large percentage of the cases treated are of chronic bone infections.—I am, etc.,

Liverpool, June 14

W. R. D. MITCHELL.

Marking of Gas-contaminated Clothing

SIR,—In many areas the handling and cleansing of gas-contaminated clothing is the duty of the district engineer, but I expect that some medical officers of health and first-aid post medical officers have taken an interest in the collection and marking of the clothing that may be handled in the cleansing stations attached to hospitals and first-aid posts.

The original suggestion was that the clothing could be marked with metal disks fastened to the garments and then collected in string bags, which could be similarly marked. It is now necessary for cotton and woollen garments to be kept separate, and it is suggested that a tape or disk be pinned to each garment. In this district we have worked out a scheme by which every garment has a tape label attached to it by a stapling machine. This altogether does away with the need for safety pins, which in practice will, in my opinion, prove unsatisfactory. The stapling machines can be efficiently handled by men or women even wearing the clumsy gas protective gloves. The scheme requires that a stapling machine, two rubber stamps, a length of tape, and a pair of scissors be supplied to each side of the cleansing station. When the station is at work every garment will have firmly fixed to it the initial of the station, the date of contamination, and the owner's number stamped upon a small tape. After decontamination it should be a simple matter to return the clothing to its rightful owner.

The advantages are that this scheme offers a simple and efficient method of marking clothing and saves innumerable safety pins.—I am, etc.,

W. F. CORFIELD,

Medical Officer of Health, Colchester.

June 27.

Diabetic Coma in Young Diabetics

SIR,—I have read with interest Dr. Leslie Cole's article on diabetic coma in a series of young diabetics (June 14, p. 882), and, while I find myself in agreement with much that appears in it, there are one or two points on which further information would be of value, and one therapeutic procedure advocated which, I think, is not without possible danger. In the description of Case 6, in which severe ketosis, as judged by urinary examination, was absent during the early stages, no mention is made of the presence or absence of acetone in the breath. I have seen several such cases, one quite recently, in which the kidneys appeared to be unable to excrete ketone bodies, but in which a strong odour of acetone in the breath left the diagnosis in no doubt. In such cases it is wise to examine the serum qualitatively for ketone bodies by Rothera's test, as this may give a strongly positive result.

Dr. Cole rightly stresses the importance of fluids and saline in the treatment of diabetic coma, the administration of which in large volumes in desperate cases was advocated by Lawrence in an article in the *British Medical Journal* of April 12, 1930, and thereby presumes the knowledge that peripheral circulatory failure is an, if not the most, important cause of death in this condition. He omits, however, in his series, to give any records of blood pressure before or during treatment, which is unfortunate because, from the point of view of prognosis and treatment, the level of the systolic pressure is of greater importance than that of the blood sugar, whose chief value is its guide to insulin dosage.

Lastly, under the heading of treatment, Dr. Cole advocates giving "usually not less than 50 units [of insulin] repeated every one or two hours according to the clinical and biochemical progress." In my experience in severe cases of coma the progress either clinical or biochemical made in intervals of one or two hours is often not significant enough to allow of its being safely used as a guide to insulin dosage, especially if such progress is apt to be the combined result of the treatment of dehydration and ketosis, a fall in blood sugar in the early stages of treatment being the outcome of an increase in blood volume as well as insulin action. But even if the progress of the case could be adequately estimated from hour to hour the practice of giving insulin at such frequent intervals is both unnecessary and unwise. Doses as large as 50 units do not exert their maximum action for at least three hours, and, consequently, if injected every one or two hours, constitute repeated additions to an amount of insulin which has not had time to show full evidence of its

action; the cumulative effect so produced not only detracts from the value of blood-sugar determinations as a guide to subsequent dosage but, in hands less skilled than those of Dr. Cole, may easily in children result in severe hypoglycaemia.—I am, etc.,

The Diabetic Department, WILFRID OAKLEY.
King's College Hospital, June 17

Chronic Sick in Bombed Towns

SIR.—The Minister of Health in reply to a question put by Sir E. Graham-Little on the subject of the "chronic sick" in bombed towns stated (*Journal*, June 21, p. 950) that he could not give "the total number of chronic sick still housed in public health and public assistance institutions," etc., "without elaborate and detailed inquiry from a large number of different authorities." The answer given by the Minister is, of course, obviously evasive, as anyone can tell from personal experience of Government Departments, especially in wartime. In other words, if the Minister really wanted to know the total number and to disclose it to the public he would soon find himself and his staff in very hot water. However, in order to help him to grasp the gravity and urgency of this question I can tell the Minister that the figure for London is about 5,000.—I am, etc.,

Criccieth, June 21.

FREDERICK MENZIES.

SIR.—Permit me to "confirm by my testimony" the existence of the disgraceful state of affairs in regard to chronic sick patients which has aroused the just anger of Sir Frederick Menzies (June 7, p. 888).

Last October I was a medical officer at a hospital for chronic sick in London—and I should explain that the term "chronic sick" was a precise, defined meaning. It means a patient who is bedridden owing to an incurable illness and is not necessarily synonymous with "senile," as might be inferred from a recent reply given in Parliament by the Minister of Health.

In that hospital we had several hundreds of such patients (over 95% of whom were unable to get out of bed) and, in spite of the fact that we were doing no air-raid casualty work, those patients, strung out on three floors, were left there night after night while bombs missed the building by 20 to 30 yards.

Two questions arise:

(1) *Ought early evacuation to have taken place?*—On balance of reasonable probabilities the building was going to be hit. This was clear to us and clear to the local police authorities, who were gravely perturbed (as I happen to know) by the plight of such a large number of helpless patients. The suggestion that it may be necessary, in the welter of competitive and even Gilbertian priorities alluded to by Mr. Ernest Brown, to leave in the vaunted "front line" such unfortunate people is an unworthy one and one which would have appalled our fathers, who had a firmer grip of the spirit of Christianity than we have.

(2) *What of the future?*—In spite of the apathy of what a modern writer has called "our deplorable Press," the problem of disposal of the chronic sick will solve itself.—I am, etc.,

Portsmouth, May 25.

J. C.

Paralysis accompanying Herpes Zoster

SIR.—The note on paralysis accompanying herpes zoster by Mr. G. I. Wilson (June 21, p. 930) suggests that this combination is not excessively rare. I think it never has been very rare, but I believe Ramsay Hunt was the first to describe it under the name "syndrome of the geniculate ganglion." There is an admirable illustration of the condition in Aldren Turner's *Textbook of Nervous Diseases* (my edition is 1910, p. 88). Another point in Mr. Wilson's note is that his patient exhibited a generalized vesicular eruption resembling chicken-pox. This is not chicken-pox but *herpes generalisatus*—a phenomenon not uncommon in old people who suffer from herpes zoster. Stelwagon in his *Diseases of the Skin* mentions this form of herpes, giving some references. I have seen five instances of the condition occurring in the seventh or eighth decade of life.—I am, etc.,

Bristol, June 21.

J. A. NIXON.

Bilateral Renal Colic due to Sulphapyridine

SIR.—I think it might be of interest to add to recent publications on this subject an observation of a case of bilateral renal colic due to sulphapyridine.

A private aged 36 was from May 1 to May 10, at the reception ward of his unit, treated for pleurisy. On May 15 he was taken ill again, and on the following day was admitted to our hospital, where the diagnosis of pneumonia of the right upper lobe was confirmed. Mild cyanosis and occasionally vomiting were noticed while on routine sulphapyridine treatment. On May 18 he complained of diffuse pain in the right hypochondrium and kidney region, radiating into the right testicle. The violent pain was controlled only after injection of morphine and atropine. On May 19 the patient experienced severe colicky pains on the left side, followed by complete suppression of urine. The total amount of urine passed in the following twenty-four hours was 3 c.cm., and this had the appearance of blood. Intensive treatment and immediate stopping of sulphapyridine was followed by rapid improvement. An x-ray film did not show the presence of calculi and there were no stones or gravel in the filtered urine, which however contained albumin for a few days. The urinary output was almost normal by May 21. The total amount of sulphapyridine given amounted to 20 grammes.

When the first attack occurred we thought of a fortuitous association of renal colic with pneumonia, as it is well recognized that febrile conditions may aggravate latent nephrolithiasis. By the following day the latter diagnosis had to be reconsidered in view of the occurrence of renal colic on the other side, with no history of previous attacks. It was felt that sulphapyridine was the responsible factor, and this view was confirmed as rapid improvement followed the discontinuation of this drug.

This short record of a case of bilateral renal colic due to sulphapyridine is an addition to the considerable number of publications of more or less serious toxic effects of members of the sulphonamide group. In my opinion more careful consideration whether treatment with these preparations is necessary should be given to all cases prior to their administration. It appears to me that the use of sulphapyridine and sulphanilamide—our most potent weapons in the fight against serious infective conditions—should be limited to those diseases where their administration is strictly indicated, or where other measures are likely to fail. The habit of using them in order to be "on the safe side" should be deprecated, and the possibility of sensitization by previous administration should be borne in mind. A common source of overdosage could be avoided if colleagues in charge of military units or in private practice would not transfer patients to a hospital without a short note regarding the amount of sulphapyridine or sulphanilamide given, and the patient's reaction to this treatment.—I am, etc.,

An E.M.S. Hospital, June 5.

EMANUEL KOST.

Medical Planning Commission

SIR.—We students in Edinburgh have been following with interest the letters and articles appearing from time to time in your columns regarding the above Commission. Like many of your correspondents we view with concern the composition of the Commission, including as it does not one medical student or recently qualified man. With as much concern we note the apathy with which medical students as a whole have so far acknowledged the presence of this Commission. We were delighted to read Mr. Kennish's letter in your issue of May 10 (p. 738), and tardily hasten to support his views; indeed, we would speak more strongly on the matter and, while fully realizing that the presence of a Medical Planning Commission does not necessarily mean that a plan will be formulated or, if formulated, will be adopted by the Government or medical profession, would point out that, even though the reports to be prepared may not be binding, they will be used as a basis for any future reorganization.

As a result, owing to the exigencies of war, a real wrong will be done to thousands of younger men, who, because they are serving with His Majesty's Forces, cannot give time or thought to the matter, or, because they are still students, cannot take an active part in planning the future of their profession. Realizing that to add more and younger men to the Commission might make it unwieldy, we have outlined the following alternative scheme for consideration.

1. That the reports of the Medical Planning Commission committees, *before* being presented to the Co-ordination Committee, be sent to medical schools, universities, and Home Commands.

2. That each of these medical schools, universities, and Home Commands form local committees, either separate or combined, depending upon size and distribution. Membership would be representative of teachers, younger members of the profession who form the majority in the Forces, and students.

3. These local committees could now, before receiving any report, review the present arrangements in this country, on the Continent, in Scandinavia, etc., as gathered from books in medical libraries and foreign medical men in this country, and so be able to give detailed constructive criticism to reports sent to them by the committees of the Medical Planning Commission.

4. The members of these local committees would be able to discuss matters informally with their colleagues, and obtain information on aspects of the profession with which they normally have little to do.

5. These local committees should make their detailed comments within one month of receiving any report. These reports could then be finally reviewed by the Co-ordination Committee of the Medical Planning Commission.

6. The extra time and work involved is comparatively slight for a scheme concerning the future health of the nation, and the criticism would be representative, wide, and considered.—I am, etc.,

Edinburgh, June 6.

J. A. WATT.

The British Medical Students' Association

SIR,—The statement of Mr. H. S. Souttar at the first session of the Medical Planning Commission that he had asked for a memorandum from the British Medical Students' Association calls for a description of that body.

Until May, 1940, the medical students of this country had no organization to represent them. It is true that before the war there was a committee of the National Union of Students, but that was concerned largely with organizing interesting but fruitless annual meetings. The outbreak of war provided many and great difficulties for London medical students, and to attempt a solution of these problems (chiefly those concerned with evacuation and A.R.P.) the London Medical Committee was formed. It was this body which last year called a general meeting of medical students at Manchester, which set up the British Medical Students' Association. The medical commission at the Congress of the National Union of Students held in Cambridge on April 2 to 6 was attended by over 160 students, and a further council meeting is to be held in Cambridge on July 4 to 6 to synthesize reports from the constituent teaching hospitals into a memorandum to be placed before the Medical Planning Commission. This conference will also be addressed by outside speakers, including Dr. Trueta on "The History of War Surgery," and Dr. K. Sinclair-Loutit on "A.R.P. and Students."

Points arising from discussion at the Cambridge Congress include: (1) changes in the medical curriculum; (2) students' A.R.P. obligations; (3) student health; (4) the future organization of medicine.

1. Changes suggested in medical teaching are: (a) A general course of biology should be introduced as a preliminary to the preclinical subjects. The Americans call it an orientation course, and its object is to give a picture of life in many different forms, rather than a detailed knowledge of a few types. (b) Closer integration of anatomy, physiology, and biochemistry, which, so far as possible, should be regarded as one subject. (c) A more realistic clinical curriculum with more stress on minor ailments and less on major surgery, which for most practitioners is less important; and a sounder grounding in general psychology. (d) More preventive medicine. This involves a new conception of medicine, a conception of disease as being due to biological and sociological causes. It involves an inquiry into the social and economic environment as part of every diagnosis. It involves a greater knowledge of social agencies—e.g., of rehabilitation, insurance, compensation.

2. Students should be used in A.R.P. schemes, preferably in their medical capacities. Teaching standards should be maintained as far as possible, in spite of evacuation. We believe that to achieve this the present hospital system should be made more flexible, that beds in municipal hospitals should

be available for teaching purposes, and that evacuation of hospitals should be carried out *before* a big raid rather than after it. The big town hospitals should be used only as casualty clearing stations.

3. Student health is naturally a subject of great interest to us. Reports from one hospital of seven cases of tuberculosis (one fatal) are worrying. We have to find out what can be done to reduce the incidence of disease among students. It is entirely up to students to do this.

4. The B.M.S.A., like most medical bodies, desires certain changes in the present system of medical organization. Although we are not finally agreed on the form such changes should take, the feeling, as clearly expressed at the Cambridge Conference, was that doctors have a service to render to the community and that they should not waste their time and energy competing among themselves as to who shall render it. Our aim must be to see that our present knowledge of preventive and curative medicine shall be applied for the benefit of everybody.

The medical profession may not be used to encountering a student organization of the nature of B.M.S.A. Student organizations have so often been regarded with suspicion or contempt and have not been given the opportunity to contribute to the solution of common problems. The invitation of the chairman of the Medical Planning Commission is, therefore, very welcome to us. It is as incorrect to imagine that students do not appreciate the achievements of their elders as it is to think that those achievements have solved all our problems. We have not only the disadvantage of inexperience, but the advantage of it. Some of the present trouble may perhaps be attributed to the fact that power has been in the hands of those whose former idealism has naturally become somewhat tarnished by the experiences of earning a living. We do not pretend that our wisdom is greater than theirs, but we do say that it is worthy of consideration.—I am, etc.,

Cambridge, June 24.

DAVID PYKE.

Ship Surgeons and the Medical Personnel on Transports

SIR,—I am much interested in Dr. James Prendergast's letter on "Ship Surgeons and the Medical Personnel on Military Transports" (June 14, p. 904), and would like to support the plea for a better understanding of the role of the ship's surgeon and a more stable position for him.

The position of the sea-going doctor has improved over many years by dint of perseverance on the part of the British Medical Association and the general recognition that the services rendered are very much more than those of merely fulfilling Board of Trade regulations. Although perhaps the more studiously minded are not attracted to the life, yet there are many medical men who go to sea who are not only keen on the sea but are also greatly interested in their profession and jealous in safeguarding its interests and upholding its fine traditions.

It is therefore a slur on the profession as a whole that the word "warned" should be used in the Voyage Regulations to which he refers, and this certainly should be altered. His reference to the S.M.O. and assistant M.O. on military transports is obviously to the point, and when one realizes that there is in addition the ship surgeon, who must sail with the ship, and probably a number of other military medical officers, it does seem apparent that there is an overlapping of duties and an easy opening for friction, not to mention the waste of medical man-power, when, as Dr. Prendergast says, there is a demand for doctors in so many places. It is not logical to call in foreign doctors to our aid when superfluous posts are being filled by our own men.

My interest has been roused in this subject because I have sailed in transports as a military M.O. and have also been a temporary ship surgeon.—I am, etc.,

London, S.W.1, June 13.

G. T. CREGAN.

Ether Convulsions

SIR,—Convulsions due to novocain poisoning are rare. I have seen but one mild and three serious cases in well over ten thousand instances where local anaesthesia has been employed. The rarity of the phenomenon, and the exact similarity in every particular of novocain convulsions and ether convulsions, may have resulted in Mr. Charles Wells's (June 21,

p. 945) overlooking the possibility of the novocain's being the cause of the convulsions in the case he quotes. The similarity of convulsions of ether and novocain is heightened by a most important practical observation. In the *Journal* of August 17, 1940 (p. 222), I drew attention to the dramatic way in which these terrifying spasms cease after injecting intravenously a small dose of evipan. In a recent case of novocain convulsions exactly the same pleasing sequel resulted. When I recorded the observation in the *Journal*, I did not know to whom to attribute this marvellous life-saving measure. I have since ascertained that the credit of advocating evipan in ether convulsions is due entirely to Mr. Dickson Wright.

I am unable to subscribe to Mr. Dickson Wright's theory of the causation of ether convulsions—that is, overheating of the body. I could prove readily that in the cases of novocain convulsions I have observed any element of overheating of the body was absent. In the case of convulsions due to ether, as Sir Robert Kelly has pointed out, by the time ether vapour has traversed the tubing leading from the apparatus it is most improbable that the vapour is much over room temperature. Thus, overheating of the body and of the anaesthetic agent is far from proven as the cause. I suggest that a common factor should be looked for in these two types of convulsions. I think it will be found in some chemical agent, common to both ether and novocain, acting on the brain stem of certain susceptible individuals.—I am, etc.,

London, W.1, June 22.

HAMILTON BAILEY.

Reactions to Morphine

SIR.—The notes on idiosyncrasy to opium have interested me because of another idiosyncrasy I met recently, which I have never seen described.

The patient was a girl of 20, dying of pulmonary tuberculosis. Other attempts at sedation having failed, pil. morph. hyd. gr. 1/4 was used. After a day or two her mother withheld the pill because it "made her eyes swell." As nothing else appeared to give relief another pill was taken, and I made a special journey to see the result. About eight hours later there was oedema of the right eyelids and over the right zygomatic process. The same effect was present on the left side to a less degree. Incidentally, the patient was lying on her right side. This phenomenon occurred every time the pill was given. Later, morph. sulph. gr. 1/4 was given subcutaneously, with the same result in shorter time.

I should be very interested to know if this effect has been observed before with any frequency.—I am, etc.,

Great Harwood, Lancs,
June 22.

WALTER CALVERT.

Benzedrine in Post-encephalitic Parkinsonism

SIR.—I am interested in Dr. H. Lovell Hoffman's article (May 31, p. 816) on the effect of benzedrine on the oculogyric crises of Parkinsonism. I have for some time been investigating the effects of benzedrine sulphate as a supplement to stramonium in post-encephalitic Parkinsonism. Though my numbers so far are not sufficient to justify publication of the results, the latter are encouraging as supporting the good results of other writers. Practically all the patients who were at a standstill with high doses of stramonium have improved with the addition of benzedrine sulphate. There has been in all cases so far considerable improvement in their lethargy, slowness, and stiffness, though the salivation has remained unaffected. The comments of some of my patients have been: "Feel that I could jump"; "Can do my housework as I should." It appears that some large-scale trials are warranted in this line of treatment of a most incapacitating disease.—I am, etc.,

Newcastle-upon-Tyne, June 12.

N. U. KHAN.

"Carriers" of Tuberculosis

SIR.—A further example of the apparent grouping of phthisis cases about a benignly infected person as described by Dr. James Maxwell (May 3, p. 665), will be found in the autobiography of Mr. Middleton Murry. Three cases are mentioned, two bearing well-known names.—I am, etc.,

Buxton, June 21.

GEOFFREY ROBINSON.

Obituary

ADAM BROWN KELLY, D.Sc., M.D., LL D.,

Glasgow

It is with great regret that we announce the death of Dr. A. Brown Kelly, which occurred at his home of retirement in Helensburgh, Dumbartonshire, on June 22, in his seventy-sixth year. Glasgow mourns the loss of this most distinguished laryngologist and otologist, whose reputation was world-wide.

Dr. Kelly graduated at Glasgow University in 1888, studied in London, Berlin, and Vienna, received the degrees of D.Sc. in 1901, and M.D., with commendation, in 1904. He became a Fellow of the Royal Faculty of Physicians and Surgeons of Glasgow in 1920, and his position in the scientific world was recognized by his university when the honorary degree of LL D was conferred upon him in 1932. He was surgeon to the ear, nose, and throat department of the Victoria Infirmary, Glasgow, for many years, and after his retirement under the age-limit regulation was appointed consulting surgeon. He was also consultant in his specialty to the Glasgow Royal Mental Hospital. His eminence in laryngology and otology was recognized by many of the European societies as well as by those at home. He was a Fellow of the Royal Society of Medicine, an ex-president of the Laryngological Section, and president of the Laryngological and Otological Section of the British Medical Association at its meeting in Nottingham in the year 1926.

As to societies on the Continent and in America, he was a corresponding member of the Society of Laryngology of France, of the American Laryngological Association, of the Laryngological Society of Berlin, and the Rhinological Society of Vienna, and an honorary member of the Austrian Otological Society. He edited the *Transactions* of the Section of Laryngology and Rhinology of the 17th International Medical Congress, London. He contributed the article on "Examination of the Pharynx, etc." to the *Encyclopaedia Medica*, and the article on "Inflammatory Affections of the Pharynx" to Latham and English's *System of Treatment*. In 1912 an international collective investigation of ozoena was organized by Prof. Alexander of Berlin. Dr. Kelly was the representative of Great Britain and the Colonies on the committee, and published in the *Journal of Laryngology, Rhinology, and Otology* three notices of the progress of the work, besides compiling a pamphlet of instructions for workers in the investigation.

It is not possible to notice all his very numerous papers contributed to both special and general medical journals. These papers and addresses, to the number of sixty at least, were presented by him afterwards, bound together, to the Library of the Royal Faculty of Physicians and Surgeons, Glasgow. He did some excellent work for the Library of the Royal Faculty; not only did he catalogue all its books dealing with his special subject but he presented steel shelves to display them in a special bay. A few selected titles of these papers will give some idea of the variety of his work. Papers on the nose include "Vasomotor Rhinitis," "Aspergillosis of the Nose and the Antrum," and "Epistaxis from the Ethmoidal Veins." His studies

of diseases of the antrum of Highmore included "Transillumination of the Antrum" and "Empyema of the Antrum in Infants." Pharyngeal diseases and abnormalities of the pharynx produced thirteen papers, all showing original and painstaking investigation. He suggested a method of recording diagrammatically movements of the vocal cords, and wrote on warfare neuroses of the larynx, and on neurological factors causing immobility of the vocal cords. Of the fifteen papers on the oesophagus, those relating to congenital stenosis and congenital shortening, and nervous affections of the oesophagus, are of special note. The Semon Lecture of the University of London, delivered in December, 1926, on "Nervous Affections of the Oesophagus," was a distinguished effort. In the presidential address to the Section of Laryngology of the Royal Society of Medicine in November, 1917, he made an eloquent plea for original investigation and research into the many unsolved problems of the specialty, and urged younger specialists to pursue their subject from the physiological and pathological standpoints. Dr. Kelly was an active scientific member of the British Medical Association. He was a frequent contributor to the discussions in laryngology and otology, particularly at Cheltenham 1901, Sheffield 1908, Newcastle-upon-Tyne, and Liverpool.

Dr. Brown Kelly evidently possessed the rare gift of scientific research, which he carried on up till a few weeks before his death. He worked in the pathological departments of the Victoria Infirmary, the Royal Hospital for Sick Children, and the Royal Infirmary, and has left a considerable amount of work completed, or nearly so. He was a quiet shy man, diffident when overlooked by others while working, and shunning the publicity of teaching students. Honours came to him unsought. He took no part in public medical life, avoiding office-holding. His only recreation, apart from pathological research, was orchestral music, for which he had a refined taste and appreciation.

Great sympathy is felt for his wife and his son and daughter. His son is in the Medical Service of the Navy. His daughter is well known in Glasgow for her skill and artistry in making pictures of pathological specimens.

Mr. LIONEL COLLEDGE writes:

The passing of Dr. Adam Brown Kelly at the age of 76 will bring feelings of profound regret to all laryngologists to whom the scientific study of their subject has any real meaning. As otology and laryngology have steadily established themselves as independent branches of medicine they have in their independence been drawn into a closer alliance. Laryngology is no longer the province of an assistant physician, nor otology of an assistant surgeon; and, although there are still laryngologists and otologists, many practitioners and even professors now combine the two functions. Brown Kelly always remained an unrepentant laryngologist, but he had a remarkable professional brother in Albert Gray, who confined his work equally to otology. They were not only contemporaries and hospital colleagues, but both spent much of their time in patient and accurate scientific observation and research; both were more than well acquainted with all the foreign work of importance and knew the men who produced it, for they both travelled; and with this broad outlook they were both men of sociable and approachable character and generous in hospitality. These two men of Glasgow for many years held a unique position in laryngology and otology, and always received the warmest welcome in London.

It was towards endoscopy and especially to the study of pathological conditions of the most baffling and elusive of all organs, the oesophagus, that Brown Kelly devoted himself in particular, and his observations on its abnormalities in childhood were made with characteristic care and deliberation. He is perhaps best known to laryngologists as the first, in conjunction with his friend Donald Paterson of Cardiff, to describe that curious form of chronic dysphagia in women, accompanied by anaemia and glazed tongue, which goes by the name of the Plummer-Vinson syndrome. Some have suggested that if this must have an eponym it should be the Brown-Kelly-Paterson syndrome, but he would have been the

last to make any such claim himself. This kindly, distinguished man will be missed wherever the laryngologists meet, but it is some consolation to think that he has not gone before he had reached a ripe age.

E. TYTLER BURKE, D.S.O., M.B.

Lieutenant-Colonel Edmund Tytler Burke, D.S.O., R.A.M.C. (ret.), died at Paignton, Devon, on June 14, aged 53. After leaving the Army he took up the study of venereal diseases and settled at Salford, where he was venereal diseases officer of the city and instructor in that subject at the University of Manchester.

He was born at Elgin on April 18, 1888, the eldest son of Mr. W. M. Burke, J.P., was educated at Perth Academy and at the Universities of Glasgow and St. Andrews, and graduated M.B., Ch.B.Glas. in 1914. He was an original member of the O.T.C. at Glasgow University. He joined the R.A.M.C. Special Reserve early in 1913 and saw much service in the war of 1914-18: in Gallipoli in 1915 as adjutant of the 40th Field Ambulance; later he was given command of the unit and promoted to major, serving in Iraq from 1916 to 1918, when he was promoted to lieutenant-colonel and served as A.D.M.S. of Forces in Northern Persia, and then in the Caucasus and as senior medical officer at Baku. He was mentioned in dispatches several times, received the D.S.O., and the Serbian Order of St. George and St. Vladimir (with swords). Besides his appointments at Salford, Colonel Burke was for some time assistant in the dermatological department of Manchester Royal Infirmary and assistant medical officer to the Northern Hospital for Women and Children, Manchester. In 1930 he became lecturer in venereal diseases at London Hospital Medical School and consultant venereologist to the public health department of the London County Council. He was a member of the British Medical Association and was vice-president of the Section of Venereal Diseases at the Annual Meeting of the Association held at Manchester in 1929. He was the author of many papers and pamphlets on his special subject.

"A. B. S." writes: Colonel Burke's interest in venereal diseases started with an early association with Dr. David Watson, and wherever his Army appointments carried, whether it was Netley Hospital, the Dardanelles, Mesopotamia, Persia, or the Caucasus, the treatment or prevention of V.D. was always uppermost in his agile mind. In 1918 while he was senior medical officer to the British troops in Baku and head of the local medical soviet his administrative abilities enabled him to organize very successfully the public health facilities, which had collapsed during the Bolshevik upheaval. His recent book, *Venereal Diseases*, has some truly revolutionary ideas. It has been said by many that Burke lived before his time, and the future alone will prove whether or no his interesting theories find acceptance. His method of assessing chemotherapeutic efficiency with his "chemotherapeutic index" has not yet met with the support in this country that it has found in America, while his statement that the gonococcus lives as a harmless symbiote in the urinary tract unless disturbed is bound to meet with powerful opposition; it is typical of Burke's fighting qualities and strength of character that he put these ideas into print.

CHARLES WILLIAM LAIRD, M.D.

Dr. C. W. Laird, Consultant Tuberculosis Officer to the Lancashire County Council, died on April 19 at Ormskirk, Lancashire, after a long illness.

Charles William Laird was born at Belfast in 1879. He had a distinguished career at Trinity College, Dublin University, winning many first-class honours and prizes in classics and modern literature. He obtained his B.A. with honours in classics in 1903, and first place at his final M.B. in 1908, with first-class honours in surgery, hygiene, medical jurisprudence and toxicology, and in pathology. At the Royal City of Dublin Hospital in 1907 he also won the Wheeler Gold Medal for first place in the examination in clinical, theoretical, and practical medicine. He took his M.D. in 1911, and the D.P.H. of the University of Liverpool in 1912.

After acting as house-surgeon at the Bootle Borough Hospital, Lancashire, Laird started his career in tuberculosis at the Whiteabbey Sanatorium, Belfast, where he was for a time

acting resident medical officer. He returned to Bootle and there held for over two years the posts of resident medical officer at the Corporation Hospital and assistant medical officer. After a further spell of sanatorium work at the Westmorland Sanatorium, Grange-over-Sands, he was in 1913 appointed one of the first consultant tuberculosis officers on the Lancashire County staff, and for a time also undertook jointly the duties of tuberculosis officer for the County Borough of Bootle. For twenty-eight years Laird was in charge of Dispensary Area 3—north, east, and south of Liverpool—containing some 200,000 acres and a population of 350,000, which included since 1924 the Rufford Pulmonary Hospital, of which he was the visiting medical superintendent. Here he did excellent work, especially with artificial pneumothorax and gold treatment. Courteous and cultured, Laird set a very high standard, never spared himself, and had as a reward the esteem and affection of all his colleagues and the medical practitioners of his area. He was a keen and good golfer, winning many prizes, and, as one would expect from an Irishman, he was an easy and excellent speaker. He leaves a widow and two sons, one following in his father's profession.

Dr. ALBERT G. W. PEARSON, a well-known and greatly esteemed West Hartlepool practitioner, died in a Newcastle nursing home on June 7 in his sixty-eighth year. Dr. Pearson graduated M.B. (with first-class honours), B.S. at Durham University in 1897. After holding house appointments at Birmingham, Sunderland, and Hartlepool, and some experience of practice at Rotherham in South Yorkshire, he established himself at West Hartlepool, where he became widely known as a skillful general practitioner surgeon and as honorary surgeon to the Hartlepool Hospital, where he had formerly been a resident. In 1925 he was joined in partnership by Dr. J. Lithgow. Dr. Pearson's entire life was devoted to his profession; he was a bachelor, and he took only a small part in public and social activities, but no call on behalf of his patients or his beloved hospital was ever disregarded. He was a man who liked to do good by stealth, and not content with giving ungrudging time and service to the hospital, he made it many substantial gifts of valuable equipment which, in accordance with his own request, received no publicity. Any spare time he had was devoted to his garden, but his real hobby, as one of his colleagues writes, was his work. The affection which a general practitioner can inspire by many years of quiet unostentatious work in his locality was illustrated at the funeral service at St. Paul's, West Hartlepool, when the entire staff of the hospital attended, as well as many representatives of civic life and of the professional and business community. Dr. Pearson was a member of the British Medical Association for thirty-five years.

Dr. WALTER ERNEST LLEWELLYN DAVIES, late of Llangitho, died at Llanidloes on June 18, aged 67. A native of Cardiganshire, he was educated at Taunton School and University College, Aberystwyth, and studied medicine at St. Bartholomew's Hospital, qualifying M.R.C.S., L.R.C.P., in 1901. He took the D.P.H. three years later, after serving as deputy medical superintendent at the Mile End Infirmary. He was then for a short time assistant medical officer at the Eastern Fever Hospital under the Metropolitan Asylums Board, and then assistant M.O.H. for the Borough of Stepney. He settled in practice at Llanidloes in 1907 and was for a time temporary M.O.H. and school medical officer under the Cardigan County Council; he was appointed district medical officer to the Llanidloes Union in 1915, and honorary surgeon to the local memorial hospital in 1922. Dr. Davies took an active part in public life, serving for two periods as mayor of Llanidloes, and he was High Sheriff of the county in 1929.

The death of Dr. SAMUEL J. BARTON, at the age of 80, removes a veteran member of the profession who was for many years prominent in the medical life of Norwich and the surrounding countryside. A student of Trinity College, Dublin, he graduated M.B., M.Ch. in 1873, and proceeded M.D. in 1885. Before settling in practice at Norwich Dr. Barton was for a time assistant physician to the Radcliffe Infirmary, Oxford. He joined the British Medical Association in 1880 and often contributed papers to the Norwich Medico-Chirurgical Society, of which he became a member after election to the visiting medical staff of the Norfolk and Norwich Hospital.

On retiring from active work he was elected consulting physician to that hospital and also to the Bethel Hospital, with which he had long been associated. He was for many years medical director of the Norwich Union Life Office. When the B.M.A. held its Annual Meeting at Ipswich in 1900, Dr. Barton held office as vice-president of the Section of Medicine. He was one of the oldest members of the Norwich bench of magistrates, and on June 24 a tribute to his memory was paid by the chairman and by practising solicitors of the court.

Medical Notes in Parliament

The Pharmacy and Medicines Bill, "to amend the Pharmacy and Poisons Act, 1933, to prohibit certain advertisements relating to medical matters and to amend the law relating to medicines" was presented in the House of Commons on June 26 and was formally read a first time. It is supported by Sir John Anderson, Sir Kingsley Wood, Mr. Johnston, Sir Donald Somervell, and Mr. Peake.

London Hospital Sectors

On June 25 Sir FRANCIS FREMANTLE inquired whether effect was to be given to Recommendations 33 to 35 of the Select Committee on National Expenditure with regard to the arrangement and administration of the London Sectors of the Emergency Hospitals Scheme. Miss HORSBROUGH replied that the extent to which effect could be given at the present time to the Select Committee's recommendations on the London Sectors was being considered in conjunction with the several officers and bodies concerned. Certain rearrangements had already been made which would reduce the number of Sectors by one as from the following week. Local authorities were being included in the discussions.

Mental Health Work among Children

Sir FRANCIS FREMANTLE asked on June 25 what arrangements were made for mental health work among evacuated children and in bombed areas, and whether assistance would be given to the Mental Health Emergency Committee for this work. Miss HORSBROUGH said mental health work among children was a normal development of the mental health services and in particular of the School Medical Service, with which child guidance clinics were associated in many areas. A number of hostels had been established for difficult children in reception areas. It was desirable that in every Region some of these hostels should be set aside for children requiring mental treatment and should be associated where practicable with child guidance clinics. A grant from Exchequer funds was made to the Mental Health Emergency Committee in respect of the year ended March 31. Application for a further grant was under consideration.

Pharmacy and Medicines Bill

According to a Ministry of Health memorandum, the Pharmacy and Medicines Bill, which has been introduced in the House of Commons, will repeal, from September 2, 1941, the medicine stamp duty and the accompanying licence duty payable by those who make or sell patent medicines. It will also regulate the sale of medicines and prohibit advertisements of remedies for certain conditions. The patent medicine duties now being given up yielded £1,400,000 in 1920-1, but at present yield only £840,000 a year. The duties are based on Acts dating from 1783 to 1812 which are full of anomalies and difficult to interpret and enforce. Under the present law doctors and chemists may sell "known, admitted and approved" remedies free of stamp duty. It has been agreed by the trade interests concerned in the sale of medicines that doctors and chemists shall have a trading privilege covering that class of remedies. The Bill accordingly provides that, while proprietary preparations not described in the *British Pharmacopoeia* or *British Pharmaceutical Codex*, and certain other types of medicine such as mineral waters and herbal remedies, should continue to be sold by unqualified retailers, all other medicines shall be sold only by doctors and chemists. The Bill also proposes that all medicines (except those made up to meet individual needs) must, on and after January 1, 1942, have on them a statement of their composition or of their active constituents. Advertisements of "remedies" for Bright's disease, cataract, diabetes, epilepsy or fits, glaucoma, locomotor ataxy, paralysis, or tuber-

Medical News

The Vegetable Drugs Committee recently set up by the Ministry of Health and referred to in the *Journal* of June 14 (p. 891) has on it the following medical men, under the chairmanship of Sir Weldon Dalrymple-Champneys: Major-General Sir Ernest W. C. Bradfield, F.R.C.S., Mr. J. M. Johnston, F.R.C.S., Dr. W. P. Kennedy, Dr. A. G. H. Smart, and Prof. L. J. Witts.

The Derry Gardens, Kensington High Street, W., will be open for the benefit of St. Bartholomew's Hospital from Monday, July 7, to Saturday, July 12, each day at 9.30 a.m. till 6 p.m., except Saturday, when they close at 1 p.m. Lord Horder opens on Monday, July 7, at 11.30 a.m., Lady Dawson of Penn on Tuesday, and Mrs. John G. Winant, the wife of the American Ambassador, on Friday.

A meeting of the Bristol Division of the B.M.A. will be held in the Physics Lecture Theatre at the Royal Fort, University of Bristol, on Thursday next, July 10, at 3.30 p.m., when there will be a symposium on "Casualty Surgery in Air Raids." All members of the Association and medical non-members will be welcome.

Benzyol cinnamate and chlorocresol (*B.P.* Third Addendum) are not chargeable with purchase tax unless put up for medicinal or veterinary use.

The honorary degree of Doctor of Science has been conferred at the McMaster University, Hamilton, Ontario, on Dr. Donald Church Balfour, director of the Mayo Foundation and past-president of the American College of Surgeons.

The Academy of Sciences of the U.S.S.R. has awarded the Pavlov prize for 1940 to Marie K. Petrova, professor of physiology in the Pavlov Institute for Physiology and author of valuable work on experimental neuroses.

The South African Institute for Medical Research in Johannesburg is about to undertake the manufacture of yellow fever vaccine under the direction of Dr. G. M. Findlay of the Wellcome Research Institute of London.

There are 7,000 doctors in Australia, of whom 500 are women, 1,170 are men over 60, and 1,500 are engaged in essential services. About 250 are medically unfit, if mobilization became necessary, for which 1,200 doctors would be required, leaving only 2,250 for the civil population of 7,000,000.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

Authors desiring REPRINTS of their articles must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be addressed to the Secretary.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES: EDITOR, *Aitiology Westcent, London*; SECRETARY, *Medisecra Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Generalized Pruritus

"K. H. P." asks for suggestions in the treatment of a woman aged 75 with generalized pruritus, thick pigmented skin in a girdle below the breasts and in the axillae and groins (which are hairless), and large patches of warty growths on the forearms, thighs, and calves. She complains also of epigastric pain and vomiting. The symptoms have extended over the past six months and have resisted all anti-pruritic treatment.

The Pain of Herpes Zoster

"F. P. L." (Cornwall) writes in reply to "M.B., B.S." (June 7, p. 876), who asked for a remedy for herpetic pain: I had a very severe attack of herpes zoster two years ago. The pain was

unbearable at times in spite of aspirin, a compound preparation of aspirin and phenacetin, and Dover's powder; even half a grain of morphine by mouth gave little relief. I then got electrical treatment by some special short-wave apparatus which had proved very beneficial in similar cases to mine; but it gave me only partial relief. Finally ionization was tried. This acted like a charm, and after three applications the pain disappeared and I have had no recurrence since then. I should be glad if your correspondent would try it and let me know through the *Journal* if the result is as good as I found it.

LETTERS, NOTES, ETC.

Coined Medical Words

Dr. S. W. SUTTON (Hook, Basingstoke) writes: Dr. W. A. Brend (June 14, p. 885), looking about for "a Greek cloak," suggests hyperphobosis (p. 887). May I suggest a slight amendment, because hyperphobosis would be a Greek blunder. It should be hyperphobesis. Let me reason from analogy. We are familiar with phimosi, which is a correctly coined word because the corresponding verb is *φίμω*. But the verb to fear is *φοβέω*, not *φοβώ*. If Dr. Brend will kindly look again at Liddell and Scott, he may see the word *ἀντιβόλησις* (antibolesis), and the corresponding verb *ἀντιβόλλω*. By analogy we should have phobesis and hyperphobesis from *φοβέω*. Kindly allow me another suggestion. Dr. Brend aptly refers us to Job iv, 13, 14: "Fear came upon me." In the Greek, fear in this verse is *φρίκη* (shuddering). While hyperphobesis is long and coined, *phriké* is short and classical.

Treatment of Burns and Blisters

Dr. J. PRICE WILLIAMS (Ambleside) writes: This deals only with a point in the first-aid local treatment of burns, and has nothing to do with the nature of any more thorough subsequent treatment. Dr. Louis Sheldon (May 31, p. 833) says "we prick all blisters." Why? There is no theoretical ground for thus interfering with the natural process of repair and the protection of the underlying raw and absorbent surface which the unbroken blister affords. The idea that the contents of the blister are immediately dangerous or likely to become dangerous in a few hours cannot be supported by any pathological evidence. As a result of practice (limited in amount but spread over a good many years) I am quite convinced that healing takes place much more favourably if blisters are left unopened until there is some definite indication that they have begun to "go wrong," and in the majority of cases of moderate severity that does not happen if the blister is cleaned externally and protected from injury. I gave up pricking blisters many years ago and have never had the slightest reason to regret it. What the surgeon in the hospital may decide to do is no concern of mine or of the first-aid surgeon, but I do maintain that the pricking of blisters as "first aid" is not only no help to him but may actually "queer his pitch" if a few hours elapse before he can tackle the case. I suggest that the pricking of blisters is meddlesome surgery, unless it is part of a thoroughly well-planned technique which can be carried out immediately, and is bad practice.

Simplified Formula for Baby Feeding

Dr. T. CRISP (Chorley) writes: I feel that the following simplified formula for baby feeding which I have used for twenty-six years will be of value to others. Children on this feeding have developed in every way satisfactorily—mentally and physically—and have also shown a high degree of resistance to disease. The first child for whom I ordered it was showing signs of rickets, which soon disappeared and he became normal in every way. During the first month, starting at seven to fourteen days from birth, take one level teaspoonful of oatmeal and pour on to it 2 oz. of boiling water; add 2 oz. of Grade A milk (or T.T.), one teaspoonful of cream, and one teaspoonful of sugar. Use a boat-shaped bottle and pass a steel knitting needle through both teats in order to permit the oatmeal to be sucked through the teat. During the second month the feed should be two level teaspoonfuls of oatmeal, 2½ to 3 oz. of boiling water, 2½ to 3 oz. of milk, one teaspoonful of cream, one teaspoonful of sugar. At the fourth month, one level tablespoonful of oatmeal, 4 oz. of boiling water, 4 oz. of milk, one teaspoonful of cream, one teaspoonful of sugar. At three to four months and onwards the child should be given pieces (too large to swallow) of raw turnip, raw apple, raw potato, or a chop-bone to suck or bite so that teething may be helped. From the first month a few drops of orange juice or grape juice may be given from an egg-spoon or even a few drops from the yolk of a soft boiled egg. A female child who was tried on every artificial food that was recommended to the mother, continued to vomit, and was 1 lb. lighter at 10 months than she was at birth, took to this feeding and has since reached adult life and is in every respect a perfectly healthy young woman, showing not the slightest sign of the early starvation. The cream can be obtained by skimming the milk.

PROBLEMS OF THE CIRCULATION*

R. J. S. McDOWALL, M.D., D.Sc.

Professor of Physiology, King's College, University of London

The honour of presenting these lectures, which have been given by many of the most distinguished names in medicine, carries with it great responsibilities, but I have at least simplified the task of choosing a subject by taking one akin to that of Oliver himself, who endowed and gave the first Sharpey lecture. In these material days a word regarding the founder may not be out of place, for George Oliver set an example by showing how the practising physician may with great advantage occupy his leisure and contribute to the advance of knowledge. Although a practitioner in Harrogate, he found time to make a most remarkable number of original observations, many of which are little known. His most notable discovery was that of the action of adrenal extracts. This he achieved by administering them to his children by the mouth and observing with his arteriometer the diameter of the radial artery, which he found to be constricted. His results are described in his Croonian lectures to this College (Oliver, 1896). The injection by Schäfer of the substance into a dog was found to cause a rise of blood pressure, and subsequently Oliver and Schäfer (1894) worked out the exact cause of this rise. Their paper is a model to all beginners, and this work started Schäfer, up to that time essentially a histologist, on an experimental career. It is a strange sidelight on human endeavour to remark that the apparatus with which the historic observation was originally made is no longer in common use, even although nothing has yet been invented to give any better information regarding the state of the arteries in man.

But Oliver did not mention these observations in his first Sharpey lectures; rather he discussed the flow of lymph, for in this field his investigations were even more extensive and just as important, although less well known. By a remarkable series of simple experiments he concluded that there must be a return of fluid from the tissues other than by the lymph, and emphasized the necessity for a variability of capillary permeability to permit this. His conception was that the tissue fluid returned to the capillaries at their venous ends, and in this he anticipated our most modern views on the subject. Some may be familiar with his ingenious haemoglobinometer and haemacytometer, with which he made extensive studies of the blood in a large number of different states, and which preceded most of the apparatus now in common use for this purpose.

Problems of Adrenaline

When Oliver gave adrenaline to the world he gave also a host of problems which have absorbed the energies of a legion of physiologists, and which will outlast our time. Many of these are not only of fundamental physiological importance but are of great therapeutic significance. It is interesting to compare the position to-day with that given by Schäfer in his Oliver-Sharpey lecture of 1908.

Further studies of the action of adrenaline have shown that its action is not so simple as at first sight appeared. The original observation indicated that the rise of blood

pressure caused by the intravenous injection of extracts of the medulla of the adrenal gland was produced by a constriction of peripheral vessels, together with an increased action of the heart if the vagus nerves were cut, but if the latter were intact the rise of blood pressure was reduced by cardiac slowing, the result of increased vagus action. These facts are not disputed, but subsequent work has shown that the doses which produce these results are much beyond that ever secreted by the adrenal glands. Moreover, it has become apparent that the essential function of adrenaline is the transference of blood from one part of the body to another and that this is not necessarily accompanied by any rise of blood pressure, for adrenaline dilates certain vessels and constricts others. Further, with such small doses cardiac acceleration is the rule, although the vagus is intact; indeed, the action of the vagus is reduced. It is possible, for example, to demonstrate in several ways a marked dilatation of the vessels of the muscles and a constriction of the vessels of the skin with doses which do not raise the arterial pressure at all.

The activity of these small doses fits much more clearly into the picture of the function of adrenaline, especially when we consider the circumstances in which adrenaline can be shown to be normally secreted—namely, mental stress, severe exercise, and exposure to cold—and this has been still further emphasized by the most recent evidence that an adrenaline-like substance, if not adrenaline itself, is liberated in the region of sympathetic nerve endings. All this agrees with the general conceptions of the action of adrenaline, which has been very much extended since the time of Oliver. Now we know that, like the sympathetic nervous system, it prepares the body for and assists in the adaptation to physical exercise. Not only does it transfer blood to the muscles from the parts of the body less used in exercise, but it throws out of action the alimentary canal by inhibiting the secretion and movements of the intestine while constricting the sphincters, it dilates the bronchi, the coronary arteries, and the pupil, and causes the liver to liberate glucose. Moreover, there is evidence (Burn, 1933) that the amount of circulating adrenaline affects the sensitivity of the sympathetic.

The appreciation of this action of small as distinct from large doses is not without considerable clinical importance, and may dispel certain misconceptions. For example, the well-known statement that chloroform plus adrenaline is very apt to bring about cardiac fibrillation probably requires modification: the experiments certainly require repetition. The whole problem of the clinical dose of adrenaline also needs consideration. Actually the usual clinical dose of adrenaline (1 to 5 minims of a 1/1,000 solution) is enormous, but fortunately it is as a rule given hypodermically. It is not surprising that the administration of a similar dose injected intravenously may have very alarming results, especially if the increased vagus action manifests itself. At the same time there is no obvious reason why intravenous therapy and the use of carefully adjusted small doses controlled by blood-pressure readings should not be more extensively used to tide over emergencies, except that the benefit would be short-lived.

* The first of two Oliver-Sharpey lectures to the Royal College of Physicians of London.

Differential Action of Adrenaline

One of the most interesting problems is why adrenaline dilates some vessels and constricts others. This differential action is probably best seen in the effects of small doses on the volume of the skinned and unskinned limb. The skinned limb dilates, while the normal limb constricts (Hoskins, Gunning, and Berry, 1916). It is true that the removal of the skin cannot be considered physiological; but a study of the venous outflow produces similar results, as does also that of isolated vessels. When we consider the problem of this differential action several possibilities present themselves, and we must remember that the problem exists not only in relation to the circulation but in respect of the other inhibitory actions of adrenaline, such as the dilatation of the bronchi and the inhibition of the intestine. Since no dissimilarity in histological structure can be discovered between the vessels which are dilated and those which are constricted, the difference may be chemical or environmental. Bacq of Liège has put forward considerable evidence that in certain organs which are inhibited there is present an enzyme which converts the adrenaline constrictor response into a dilator one. These experiments are extremely difficult to repeat, possibly because the exact conditions needed are not well enough known. Another possibility suggested by experiments on isolated vessels is the calcium-potassium balance and the acidity, acting separately or together. It would appear reasonable to imagine that the environment of the vessels of the skin is in both these respects materially different from that in the more active muscles. On the other hand, it has been demonstrated (Cow, 1911; Argyle Campbell, 1911) that vessels taken from different parts of the arterial tree behave differently though treated similarly. The problem is still further complicated in that the adrenaline reaction is also affected by the tone obtaining in the vessels at the time. Thus the dilator response of the vessels of the muscles to adrenaline by denervation is abolished (Hartman and Fraser, 1918) and may be reversed by section, in the cat, of the abdominal sympathetic, causing a relaxation of its normal tone, which we believe is kept up by the liberation of adrenaline at the sympathetic nerve endings. The dilatation, however, will return in from two to ten days when the vessels have regained their tone (Dale and Richards, 1918; Hartman, Kilborn, and Fraser, 1918), and even in isolated vessels if special steps are taken to maintain tone, such as adding adrenaline and red blood corpuscles to the perfusion fluid (Dale and Richards, 1918) or by perfusing with a calcium-free fluid (McDowall and McWhan, 1937). It would appear, then, that the nature of the response to physiological doses of adrenaline depends on the state existing in the muscle at the time the adrenaline is applied. It seems not improbable that the problem of adrenaline reversal and differential action is closely bound up with that of the intimate nature of muscular contraction itself.

Origin of Adrenaline

Another problem in relation to adrenaline is its exact origin. We know its chemical constitution and its relation to tyrosine, and the evidence is very considerable (Burn, 1933) that dioxypheylalanine is an intermediate product, but we still do not know all the steps in its normal formation. The solution of this problem is obviously of great clinical importance, as it might become possible to supply the body with chemical substances which facilitate the formation of adrenaline and thus enhance many reactions which, in some persons, especially the debilitated, appear to be deficient. It may be that a study of the steps in the formation of the adrenaline-like substance in common

broom (Gorrill, D'Silva, and McDowall, 1935) may throw light on the subject.

The problem of the destruction of adrenaline is no less important, for by preventing it, in a way similar to the enhancement of the action of acetylcholine by eserine, we might be able to prolong its activity and thus greatly increase its value; for the rapid destruction of adrenaline is its greatest disadvantage in therapeutics. A considerable amount of work has been done on the subject, notably by Heard and Welch (1935) and by Richter (1940), which at present is only of academic interest, but which shows that enzymes are involved in the destruction of adrenaline, and that this destruction may be reduced by compounds containing the SH group. According to Gaddum (1939), ephedrine inhibits the action of the destroying enzyme.

In the Oliver-Sharpey lectures of 1939 Gunn indicated that the many substances which act somewhat like adrenaline depend for their action on a similar chemical structure. Such work shows that it is possible to design new substances which may have the same action as but are less easily destroyed than adrenaline itself. So far these are little more than laboratory investigations, but the results indicate that considerable progress of great clinical importance may be anticipated.

Thus it is quite fair to say that Oliver by his discovery of the action of adrenal extracts showed us a new and undreamt-of world, and at the same time made us aware of even more undreamt-of secrets.

Function of the Carotid Sinus—a New View

When the activity of the carotid sinus at the bifurcation of the common carotid was discovered by Hering in 1923 it was almost taken for granted that its function was the maintenance of the arterial pressure at a constant level, the more so as such a function had already been admitted for the aortic depressor nerve. The evidence on which this view rested at first appeared unequivocal. Briefly, it was this: The lowering of the blood pressure in the sinus or painting it with cocaine resulted in a rise of arterial pressure and cardiac acceleration, while a raising of the intrasinus pressure or mechanical stimulation of the area had the opposite result—namely, cardiac slowing and vasodilatation. A remarkable series of experiments, especially by Heymans and by Koch on the isolated sinus attached to the body only by nerves, seemed to put the matter beyond dispute.

A general study of the problem, however, especially in more intact animals, has indicated that it is not so simple as at first sight appears; indeed, already it has become evident that the above theory of the function of the sinus is certainly incomplete and may in part be quite erroneous. The experimental findings are not disputed, but when they are taken into consideration with many of the other known facts of the circulation, the so-called "buffer action" of the aortic and carotid nerves becomes not a little reminiscent of the "phlogiston" theory of oxidation and respiration, in which the significance of the facts, especially the role of carbon dioxide, became almost inverted.

A few general facts regarding the circulation are outstanding, and of these the most important is that the blood pressure rises normally in man and animals in spite of the carotid and aortic reflexes. This rise occurs typically in mental stress and in exercise, and is accompanied by cardiac acceleration. Moreover, the arterial blood pressure is maintained at a constant although higher level, after section of the carotid and aortic nerves, in spite of changes of posture and small amounts of haemorrhage.

If the effects of haemorrhage on the reaction of the carotid sinus are studied in animals in good condition most

unpredictable results are obtained. It might be expected that a fall of pressure in the sinus would bring about generalized vasoconstriction and the recovery of the blood pressure until all the vasoconstriction was used up, as it were. This is the general idea that may be read in most descriptions of the function of the sinus. Experimentally, just the opposite occurs. The blood pressure may fall 25% without the carotid sinus apparently taking any action in its recovery; indeed, the response to occlusion of the carotid may at first be even greater than before. The blood pressure may, indeed, be reduced by 30% before there is a significant fall in the responses of the sinus; while vagus restraint, which we believe is dependent on the depressor reflexes, although reduced, is still retained. A study of the currents of action of the depressor nerve indicates that if a fall of blood pressure is caused by placing the animal in the feet-down posture the electrical changes are reduced for a very short period but are resumed although the arterial pressure is low (Greenwood and McDowall, 1937). It would seem very doubtful whether the recovery from haemorrhage, at least from small amounts, involves the carotid sinus mechanism at all. All that can be demonstrated is that the reactions of the vasoconstrictor centre to falls of pressure in the sinus are increased. This is seen in the increased rises of arterial pressure which occur if the sinus is occluded and by the increased constriction of the spleen and the intestine.

Function of the Depressor Reflexes

We may ask, What, then, is the function of the depressor reflexes from the carotid sinus and cardio-aortic region? A clue would seem to be given by a detailed study of reactions of the aortic depressor or of the sinus, the nerve from the sinus being difficult of access. It is now evident that all procedures which reduce the restraining influence of the vagus on the heart reduce the reaction to carotid occlusion. Of these the most notable are a rise of venous pressure and the injection of small amounts of adrenaline, following which the response of the sinus to carotid occlusion is reduced and may even be abolished for a short time after the arterial pressure has returned to normal. Now, it has been amply shown that the normal vagus restraint of the heart is dependent on the depressor reflexes from the sinus and aorta, and that the most important cause of the acceleration in exercise is a reduction of vagus action. It is but a step to imagine that at the same time the vascular component of the depressor reflexes is reduced also, and that circumstances which reduce vagus restraint reduce general vasodilatation also. Thus as the heart beats faster the blood depots constrict and return more blood to the heart.

It appears, then, justifiable to assume that the function of the depressor reflexes is not to prevent a rise of blood pressure but actually to facilitate such a rise, just as the cardiac inhibitory reflexes through the vagus do not prevent normal cardiac acceleration but, by producing a low resting level, confer on the heart a larger range of activity.

Various other pieces of evidence go to support this view. Bayliss, for example, found that stimulation of the aortic depressor nerve resulted in a fall of both arterial and venous pressures—i.e., a greatly increased capacity of the circulation—while it may readily be shown that the reverse occurs on cutting out the sinus. Recently Barry and Loughnan (1941) have demonstrated that carbon dioxide causes a reduction of the activity of the depressor nerve relative to the activity of an ordinary pressor nerve.

It may well be asked how this view of the carotid sinus action was overlooked by Continental workers; but the explanation is clear. In their desire to obtain the maximum responses from occluding the sinus the aortic depressor

nerves were cut at the same time—i.e., all the depressor reflexes were cut off suddenly and simultaneously—with the result that such an intense increase of the peripheral resistance occurred that there was a cardiac failure and, according to Heymans in his monograph, an accumulation of blood in the arteries—a fact which is a little difficult to conceive. If, however, less drastic procedures are adopted it is easy to demonstrate that there is a rise of venous pressure and increased cardiac output—a view with which Heymans subsequently agreed.

In exercise, then, it may be considered that the reduction of the sinus reflexes not only promotes acceleration of the heart but at the same time constricts the blood depots and makes more blood available to the active muscles. Thus we may understand that the right auricular reflex of Bainbridge, by which an increase of venous pressure reduces vagus restraint, also has a vascular component, and experimental evidence of this has already been put forward (McDowall, 1934).

The acceptance of this view of the function of the carotid sinuses has some important clinical corollaries. We see, for example, why it is that mental stress, such as that of recruits for the Services undergoing medical examination, a rise of systolic but not of diastolic pressure is commonly found. This must be produced by an increased output of the heart per beat, and, for reasons just indicated, is easily explicable as a result of reduction of the activity of the depressor reflexes and of more blood being returned to the heart. It would seem, too, that the depressor reflexes, by controlling the blood depots, make available a large quantity of blood which is available not only for exercise but for areas demanding blood, as in inflammation. All this conception of the function of the sinus depends on the existence of a circulation of variable capacity.

(The second of these lectures will appear in next week's issue with a short bibliography.)

THE LOCAL TREATMENT OF BURNS

BY

R. S. BRUCE PEARSON, D.M., F.R.C.P.

E. E. LEWIS, F.R.C.S.

AND

R. B. NIVEN, B.M., B.Ch.

Medical Officers in the E.M.S., King's College Hospital

In dealing with patients suffering from burns two separate problems arise—the treatment of shock and the local treatment of the burnt areas. This paper is concerned only with the latter. Two recently introduced methods of treatment have been mainly employed, and these have been compared with each other and with other better-known methods.

The irrigation envelope introduced by Bunyan (1940) has been used for treatment of burns involving the limbs and the trunk, while the application of sulphanilamide powder and tulle gras as recommended by Matthews (1941) has been employed mainly for faces, but also for burnt areas on the limbs and trunk. In addition tannic acid and triple dye have been used. A brief description of the technique employed by us is given.

Technique

In all cases except two the burnt area was thoroughly cleaned under an anaesthetic as soon as the patient's general condition permitted. Soap and water or, in some cases, ether soap followed by spirit was used for this

purpose. Dead skin was cut away. These procedures were carried out with the least possible trauma, but preliminary cleansing was thorough. When the irrigation envelope was used any unburnt areas of skin to be enclosed in the bag were washed and, in the case of hands and feet, the nails were cleaned so far as possible.

The Irrigation Envelope.—After cleansing sulphanilamide powder was liberally sprinkled over the burnt area and the bag was then drawn on and fixed in position with adhesive webbing. Care was taken to avoid applying this too tightly in the case of limbs lest it should increase the oedema of the burnt area. The patient was then left for twelve hours, after which any oedema fluid that had collected was drained off and the first irrigation with electrolytic hypochlorite solution ("milton") carried out. This was used in the strength of 2½% of the actual solution supplied, made up with water, and when the envelope was nearly full a 5% solution was run in. The limb was immersed for twenty minutes or until pain was complained of. The irrigation was repeated two or three times daily. It has been found that the average life of a bag is two to three weeks, after which leaks appear. The application of a fresh envelope is often helpful, since it gives an opportunity for light mechanical cleaning of the burnt area, the removal of infected mucus with sterile gauze, and, in the case of deep burns, the removal of necrotic areas of tissue with scissors and forceps.

Sulphanilamide and Tulle Gras.—The cleansed area was thickly covered with sulphanilamide powder and tulle gras was stretched firmly over it in overlapping strips. A fresh application of powder was then made, and several layers of gauze superimposed and lightly held in position with a bandage or face-mask. The next day the gauze was usually moist with exuded serum. It was then removed and fresh powder applied to the tulle gras, followed by clean gauze. This is not necessary in every case, but the dressing should always be removed down to the tulle gras on the fourth day, as otherwise small areas of sepsis may be found to have developed unnoticed. If septic areas were seen the tulle gras over them was removed, they were swabbed with antiseptic solution, and fresh powder and tulle gras applied. In the case of uninfected superficial burns the tulle gras was removed after from five to seven days, when healing had occurred.

Tannic Acid and Triple Dye.—Tannic acid was used in a strength of 15 or 20%, being painted with a brush or sprayed on to the burnt areas after cleaning. Triple dye was applied with a brush. These processes were repeated until a firm crust had formed, when the tanned areas were left exposed to the air so far as was possible.

Depth of Burn.—In our experience the exact estimation of the depth of burning is very difficult to determine, since burnt areas are rarely involved to an equal extent over their whole surface. Moreover, what appears to be a superficial burn at the time of cleaning may subsequently prove to be much more severe owing to coagulation of protein in the deeper layers of skin. It is, however, easy after some days to distinguish surface burns which are superficial enough to allow regeneration of skin to take place from below, and deep burns in which the epidermis has been totally destroyed, so that regeneration can occur only by ingrowth from the healthy skin surrounding the burnt area. A surface burn, even if only of second degree, may, however, be converted to a deep burn as the result of sepsis, and must then be regarded as "a secondary deep burn."

The results of treatment are therefore arranged under three headings—superficial burns (first, second, and third degree), deep burns (fourth and fifth degree), and secondary

deep burns. We have records of 19 cases treated by various methods since October, 1940. Of these, 17 were originally superficial; 4, however, subsequently became infected, and are classed as secondary deep burns. One patient had superficial burns of the face and right hand and deep burns of the left forearm and hand, and his case is classified under both superficial and deep burns. There were thus three primary deep burns. Superficial burns were left to heal naturally by re-epithelization; but the treatment of deep burns, whether primary or secondary, was directed towards obtaining a clean surface suitable for skin grafting at the earliest possible moment. That inefficient treatment of superficial burns may, as the result of infection, lead to gross scarring and perhaps the development of a useless limb is well known, but cannot be stressed too much.

In comparing the progress of burns on two limbs treated by different methods it must be remembered that the more extensively burnt limb is also, as a rule, rather more deeply burnt. When hands and face are burnt while extinguishing an incendiary bomb the face is almost always less severely affected than the hands. Moreover, the face, except for the ears, tends to heal rapidly owing to its good blood supply, while the dorsum of the hand or foot, where the skin is only loosely attached to the underlying tissues and where the blood supply is poor, takes relatively longer. In addition, where the skin is thick, as in the palm of the hand, the depth of the burn will be relatively less than where it is thinner, as on the dorsum.

Superficial Burns

Of the 13 cases under this heading, the burns in 8 were acquired while dealing with incendiary bombs, 2 were due to an explosion in a gas oven, and 3 were caused by scalding with boiling water. Eight cases with burns of the face were treated with sulphanilamide and tulle gras, and these were healed within five to fourteen days, with one exception. This man developed a mild but persistent infection of the forehead and required sixty-four days before healing was complete. Eight limbs were treated in the irrigation envelope, and required from nine to thirty-two days for healing; extensively burnt hands—one of which was completely "degloved"; and two almost completely—took twenty-one, twenty-two, and twenty-three days to heal. Sulphanilamide and tulle gras were used on ten limbs that were less extensively burnt, and the time required for healing varied from twelve to twenty-eight days. Tannic acid or triple dye was employed on small areas in three cases, which required fifteen, seventeen, and thirty days before healing was complete. In addition, tannic acid was used in three of the cases of more extensive superficial burns, all of which became badly infected; these are further discussed under the heading of "Secondary Deep Burns." Details of the progress of selected cases are as follows:

Case 1.—A woman aged 29 was admitted on December 27, 1940, having received superficial burns on the right side of the face and anterior aspects of both legs from the effects of an explosive incendiary bomb. The blistered area on the right leg extended from just below the knee to the dorsum of the foot and covered an area roughly twice that of the left. There were no signs of shock. The burnt areas were cleaned under an anaesthetic and the blistered skin removed. The face, which was denuded from the nose to the left pinna, including the forehead on that side, was dressed with sulphanilamide and tulle gras. The right leg was placed in an irrigation envelope and the left was treated with 15% tannic acid. During the next two days some pain was felt in the tanned leg and the skin was sore to the touch around the tanned area. No pain was felt in the face or right leg. When the tulle gras was removed from the face on the seventh day the underlying skin had completely healed. On the tenth day the irrigation envelope was removed and new epithelium was found to have covered the burnt area. The tan was still adherent to the left leg and could not be removed until January 29, 1941, nearly five weeks after its application. (Figs. 1 and 2.)

This case shows well how even when tannic acid is applied to a small superficial burn, and when no subsequent infection develops, the time taken before epithelial-

FIG. 1.—Case 1. Showing complete healing of superficial burn on right leg after nine days' treatment in irrigation envelope. Tannic acid is still adherent to smaller burnt area on left leg; this did not separate for nearly five weeks.

FIG. 2.—Case 1.

FIG. 3.—Case 5.

FIG. 4.—Case 8.

tion is complete under the tanned area is considerably longer than for a larger area on the opposite limb treated in the irrigation envelope. If, in addition, a surface overlying a joint is affected the immobility enforced by the tannic splint must greatly delay recovery of function.

Case 5.—A man aged 44 was admitted on December 8, 1940, with burns from an incendiary bomb involving the entire face and both hands and forearms (Fig. 3). There was complete "degloving" of the right hand, leaving a bleeding surface; the left hand was less extensively burnt. He was anaesthetized and the burnt area cleaned within five hours of admission; the face was treated with sulphanilamide powder and tulle gras, the right arm with an irrigation envelope, and the left hand with strips of lint soaked in 2% sodium bicarbonate. He subsequently suffered from shock and required a litre of plasma, given intravenously. Four days later both hands were forming new epithelium, especially the palmar aspect of the hand enclosed in the bag, but this hand was more oedematous than the left. There was no pain in either hand. Cultures taken at this time showed a scanty infection of the left hand with Gram-positive cocci and bacilli, while exudate from the bag grew *Staph. aureus* and haemolytic streptococci. The face was still oedematous. Nine days after admission the face was healed except for one or two scabs round the hair margin; the left

hand had become sodden and was dressed with sulphanilamide and tulle gras. After fourteen days the bag was removed from the right arm and the burnt area was found to be almost entirely covered with epithelium except for the flexor creases of the fingers and an area on the back of the hand. Movement was limited by oedema. A new bag was now applied. After sixteen days the left hand was healed except for small areas on the dorsum of the distal phalanges of the third and fourth fingers; movements were almost full. Three weeks after admission the bag was finally removed from the right arm which had healed. Movements of both hands were good but not yet full. When seen three months later both hands had full movement and power and were covered with healthy skin except for a small area with early keloid changes on the ulnar border of the left hand and on the right wrist.

The rapid healing of the extensively burnt right hand in the irrigation envelope, in spite of moderate infection, is noteworthy.

Case 8.—A youth aged 19, admitted on March 8, 1941. This patient was burnt as the result of an explosion occurring in a gas oven. The skin over the face and of both hands and wrists was blistered (Fig. 4). The loose skin was removed under anaesthesia, the face was treated with sulphanilamide and tulle gras, and both hands were fitted with irrigation envelopes. After nine days the bags were removed and the burnt areas of both hands were seen to be covered with a layer of mucopurulent exudate. On culture, *Staph. aureus* was grown. There was some oedema, preventing full flexion of the fingers and in all respects no obvious difference between the two hands was observed. A fresh irrigation envelope was now applied to the left hand, while the right was dressed with sulphanilamide and tulle gras, leaving the ends of the fingers and thumb exposed. From now on this hand was used for feeding and other minor activities. It was next dressed on March 20, twelve days after admission, and was then healed except for a small area on the dorsum. The left hand, in the irrigation envelope, was more oedematous and had not reached such an advanced stage of healing. On March 30, three weeks after the injury, the right hand was quite healed, and when the left was removed from the bag there was an extensive scab over the dorsum that did not separate until thirty-two days after the injury.

Although both hands were at first treated identically, after a week direct comparison was made between sulphanilamide and tulle gras and the irrigation envelope. In this case there was no doubt that more rapid progress was made with the former method, although both were satisfactory. From the moment the right hand was dressed, leaving the finger-tips exposed, the patient began to use it, whereas, in spite of frequent encouragement, the hand enclosed in the irrigation envelope was left passive except during irrigations. To this the rapid subsidence of the oedema of the right hand is attributed. Moreover, while only three dressings weekly were required for the hand treated with sulphanilamide and tulle gras, thrice-daily irrigations were necessary for the hand enclosed in the irrigation envelope.

Deep Burns

Two of these 3 patients were burnt in coal fires—one following an epileptic fit, the other after the destruction of her house by a bomb. The third case was due to explosion in a gas oven. All 3 had severe burns of one upper limb, including the hand in 2 cases. They were treated in irrigation envelopes until necrotic tissue had separated sufficiently to allow grafting to be carried out. The time necessary for this was forty, fifty, and twenty-eight days respectively. The epileptic patient also had deep burns of the face and breast; these were treated with tannic acid 20% and triple dye. Infection of these areas developed, necessitating painful daily dressings, which were in marked contrast with the painless treatment of the equally burnt area in the irrigation envelope. The bomb victim had a circular burn around the forearm and involving the palm of the hand—the skin and subcutaneous tissues were destroyed, exposing muscle tissue and the radius. Case 9, in which there were superficial burns of the face and right hand (Fig. 5), was ready for grafting after twenty-five days,

but the development of a sore throat caused this to be delayed.

Case 9.—A man aged 23 was admitted on March 8, 1941. He was involved in the same accident as Case 8, but was nearer the oven and was more seriously burnt. He was considerably shocked and required plasma transfusions. His face was treated with sulphanimide and tulle gras, and both arms were placed in irrigation envelopes. The left was much more extensively burnt than the right. After cleansing and removing burnt skin there was no apparent difference in the depth of the burns on the two hands, but in the course of the first week it became evident that the left hand and arm were burnt more deeply than the right. Whereas re-epithelization of the latter began

FIG. 5.—Case 9.

FIG. 6.—Case 16.

after four or five days, the epithelial tissues of the left forearm and hand then began to separate, leaving an area of granulation tissue. This extended round the forearm except for one area of unburnt skin beneath the wrist-watch and its strap, and involved the dorsum of the hand. Two weeks after admission the right hand was healing well, but necrotic skin was still separating from the left forearm. Twenty-three days after admission the right hand had healed except for an area the size of a sixpence over the fourth metacarpo-phalangeal joint. The left arm and hand showed some growth of new skin, especially on the palmar and ulnar edges of the hand and fingers, but most of the burnt area presented a raw granulating surface. Sulphanilamide and tulle gras were now applied to this limb, and twelve days later Thiersch grafting of both aspects of the forearm and the dorsum of the hand was successfully carried out (E. E. L.).

This case demonstrates the early difficulty in determining the depth of the tissue damaged by burning. The irrigation of the more deeply burnt limb in the envelope was valuable in assisting the separation of the necrotic skin and preparing a suitable surface for grafting.

Secondary Deep Burns

Two of these patients were burnt through the explosion of an oil bomb, one from a scald, and one in a manner unknown. Tan or triple dye had been used as the initial treatment in three of them. In one case the skin was blistered but not broken. This was removed and triple dye applied directly without further preliminary cleansing. The tanned area became infected, and was eventually grafted after thirty days (E. E. L.). The fourth case was admitted with superficial burns of the face, both forearms and hands, and the anterior aspects of the legs, due to the explosion of an oil bomb. These areas were cleaned with saline without an anaesthetic and dressed with foille and later with eusol and saline compresses. The legs were healed in seven weeks, and the face and arms in from eight to ten weeks, areas on the forehead and left elbow having been grafted a month after admission. The slow progress in this and the preceding case was almost certainly due in part to the inefficient initial cleansing. The history of Case 16, the most extensively burnt case in the series, is as follows:

Case 16.—A boy aged 14 was admitted on October 15, 1940, with extensive burns involving the back from neck to wrist, the left arm to the wrist, the right forearm and hand, and part of the left side of the face, as the result of the explosion of an oil bomb (Fig. 6). The skin of the back was severely blistered, but the burns nowhere appeared to be more than third degree. He was at first very little shocked, and cleansing under anaesthesia was carried out two and a half hours after the injury. 20% tannic acid was applied. Later in the day the blood pressure dropped to 85/65 and over two litres of plasma was given intravenously. In the course of the next week sepsis

developed under the tan on the back and on the left arm, and the tan itself began to strip off, being removed piecemeal. The temperature rose to 103° at night, and the pulse rate varied between 105 and 130. Eusol dressings were applied; but their removal was extremely painful, and more than two hours was spent over each dressing. Immersion in a saline bath was attempted, but this led to exhaustion and to an increase in temperature. Early in November liquid paraffin and brilliant green 1% were applied, and the burnt area of the back was left exposed to the air. This was followed by some improvement, and epithelization occurred over the centre of the back and the upper part of the shoulders. The rest of the back was covered with infected crusts, and the left arm and flank were painful and heavily infected. The temperature still rose to 100° at night, and the pulse rate varied between 120 and 130. The face and left arm where the tan had not been disturbed by sepsis were now healed except for the edge of the left pinna. At this stage (November 10) an irrigation envelope was applied and thrice-daily washings with dilutions of electrolytic hypochlorite solution (milton) were carried out. Considerable pain was experienced when the strength of this solution exceeded 1%, and it was therefore kept below this. During the first week the infected area became cleaner, epithelium spread in from the healthy skin edges, and numerous small islands of epithelium appeared in the middle of the raw areas. After a week the condition became stationary and then began to retrogress, the new skin becoming absorbed, the raw areas being bathed in pus an hour or two after each wash. The general condition was unaltered. On December 4 the bag was removed, the infected areas were washed for twenty minutes with 10% milton solution under gas-and-oxygen anaesthesia, and a fresh bag was applied. From this time healing continued favourably. A maximum final strength of from 2½ to 4% milton solution was reached in the bag at each wash. This was definitely painful, but seemed to cause no more pain than 1% had previously. Progress was accompanied by an improvement in general health, the temperature falling to a maximum of 99° and the pulse rate to the neighbourhood of 100. By January, 1941, the back had become largely epithelized, but there were fresh signs of reabsorption in some areas. The envelope was therefore removed and tulle gras and sulphanimide powder were applied. The condition improved, epithelization continued, and on January 24 areas on the left arm and shoulder were grafted (Thiersch and pinch grafts—E. E. L.). On January 30 the grafts were found to have taken well, but there was some infection of the ungrafted granulation tissue of the left flank. Diphtheroids, *Staph. albus*, and *Staph. aureus* were grown on culture. In spite of repeated applications of sulphanimide and tulle gras the infection spread, and large areas of newly formed skin broke down. Raw areas varying in size from a sixpence to a half-crown developed on both sides of the back. In spite of various antiseptic dressings it appeared as though the whole burnt area would shortly be involved and all the new skin reabsorbed. On February 17 the back was washed with 10% electrolytic hypochlorite solution (milton) in water under anaesthesia and a fresh irrigation envelope was applied. Within two days the temperature, which had risen again to 100° at night, fell, and the pulse rate dropped from 100 to 80. Rapid re-epithelization took place. This continued until March 11, when the bag was again removed, sulphanimide and tulle gras were applied to the remaining raw area of the left arm and back, and new Thiersch skin grafts were made. These again took well, and by mid-April the back was healed except for a few small areas. Complete healing had occurred early in May.

This case reveals a number of important points. While it is possible that the original application of tannic acid to the extensive burnt area actually saved this boy's life by diminishing the absorption of toxic products, the subsequent infection beneath the tan reveals one of the disadvantages of this form of treatment. During this time what had originally been a superficial burn was converted into an infected area involving the entire depth of most of the epithelium. The use of the irrigation envelope was at first followed by striking improvement in the local condition, great relief of pain for the patient, and considerable time-saving for the nursing staff. The improvement was not maintained, probably owing to the great dilution of hypochlorite used in the wash-outs. Further cleaning with stronger antiseptic and the use of a higher concentration of hypochlorite for the irrigations led to the re-establishment of progress locally and marked improvement in the general condition. Even so, however, organisms (*B. pyocyaneus* and *B. coli*) which were apparently "fast" to hypochlorite

eventually gained ascendancy and reabsorption again occurred. A change over to sulphanilamide and tulle gras was at once followed by improvement, but again organisms (*Staph. aureus*, *Staph. albus*, and diphtheroids) "fast" to sulphanilamide became established after some weeks, leading once more to retrogression. This was halted by reverting to the use of the irrigation envelope and hypochlorite. After the first few days this patient always complained of pain, often severe, during and for some minutes after irrigation.

It is probable that in a case of this type with an extensive, deep, and infected burnt area inevitably requiring some months for recovery, no single method of treatment would have been effective. A change was essential from time to time, and the most rapid progress was noticed to take place always during the two weeks immediately after such a change, whether it was due to hypochlorite or sulphanilamide; this was followed by a period of slower improvement, and then by definite retrogression. The use of the irrigation envelope in this very difficult case contributed materially to ultimate recovery.

Bacteriology

Irrigation Envelope.—Infection of the burnt area was always present to a variable extent, and even prolonged contact with 5% electrolytic hypochlorite solution was not sufficient to abolish it. Thus in one case swabs taken from the burnt area after the initial cleansing were sterile. Three days later occasional Gram-positive cocci were seen in a smear, and scanty colonies of *Staph. aureus* and haemolytic streptococci were grown on culture. Four days afterwards coliform organisms were also present. Smears from the leg of Case 1, taken three days after admission, showed leucocytes but no organisms; on culture *Staph. albus*, diphtheroid organisms, and *B. subtilis* were grown. In another case purulent exudate always collected in the bag overnight, and haemolytic streptococci and *Staph. aureus* were found a week after its application; a fortnight later haemolytic streptococci and *B. pyocyaneus* were grown, and a culture taken when the bag was finally removed before skin grafting, six weeks after admission, showed a heavy growth of *Staph. aureus*, *B. pyocyaneus*, and *B. proteus*. The difficulty of abolishing an established infection was further shown in Case 16, in which absorption of newly formed skin was observed to be taking place two weeks after the bag was first applied: about half a pint of pus was then collecting in the bag overnight. Smears showed a moderate concentration of organisms, and on culture haemolytic streptococci, diphtheroids, and *B. proteus* were grown. The bag was removed on December 4 and the back and arms were washed with 10% hypochlorite solution for twenty minutes. At the end of this time they appeared clean, and there were numerous capillary haemorrhages on the granulating surfaces. During the next five days three washings daily with 2% and 3½% hypochlorite solution were carried out. On December 9 there was no significant reduction in the number of organisms, and *B. proteus*, diphtheroids, and *Staph. aureus*, with occasional colonies of haemolytic streptococci, were cultured.

Sulphanilamide and Tulle Gras.—When sulphanilamide powder and tulle gras dressings have been applied to a well-cleaned surface, infection has been minimal but has not always been prevented. Thus in Case 5 a smear taken from the face five days after admission showed a moderate infection with organisms of the *B. coli* group, *Staph. albus*, and diphtheroids. Again, a swab from the back of Case 16 taken a week after the removal of the bag, during which sulphanilamide and tulle gras had been applied, showed a sparse growth of *B. coli*; after three weeks *Staph. aureus*, *Staph. albus*, and diphtheroids were cultured. In other

cases *Staph. aureus*, *Staph. albus*, and *M. tetragenus* have been cultured and proved resistant to further treatment with sulphanilamide. Both methods appear to limit infection, but with each of them, when infection becomes established, a change in the treatment is necessary to control it. Streptococci, diphtheroids, and *B. coli* were commonly grown from patients treated with hypochlorite solution, and staphylococci from those with sulphanilamide. Whichever method is employed the initial cleansing of the burn is of great importance.

Pain

Treatment with the irrigation envelope has been relatively painless. The majority of patients have had no pain throughout and have been able to tolerate irrigation with a mixture containing up to 1 oz. of electrolytic hypochlorite solution to the pint of water (5%) without more than a slight tingling. In some cases, however, pain has been complained of. This may occur during or after irrigation. In Case 16 a concentration of electrolytic hypochlorite solution of more than four ounces to twenty pints of water (1%) caused pain throughout treatment. Two other patients with burns on the hands also complained of pain during irrigation with 2½% solution; in one of these there was considerable oedema of the arm, probably due to too firm an application of the adhesive attachment, which was considered to be partly responsible. In the other no obvious cause was discovered, but it was subsequently found that half-strength eusol dressings were equally painful. In one case, although irrigation could be carried out painlessly with 5% solution, severe pain developed in the burnt area from half an hour to one hour after the irrigation was over. This ceased after three or four days of treatment. Treatment with sulphanilamide and tulle gras has been almost entirely painless.

Conclusion

Two new methods of treatment of burns have been investigated and both have been found to possess advantages over older methods. For superficial burns of the face or limbs the use of sulphanilamide and tulle gras has been especially successful, and rapid healing, with good function, has resulted. In some cases, however, infection, usually with staphylococci, has supervened, necessitating a change of antiseptic. This treatment is almost painless, and in many cases need only be carried out every few days. It is the most practical and efficient method for routine use in superficial burns of moderate extent. The irrigation envelope is useful for more extensive burns, and for deep burns in which separation of necrotic tissue must take place before grafting is possible. The burnt area can be readily inspected, and free and painless movement of limbs, fingers, etc., can be carried out during irrigation. The treatment is not always painless, and infection is controlled less well than with sulphanilamide. The application of the adhesive seal round the limb may increase the oedema of the burnt parts unless great care is taken. In some cases a change from one method to the other has been used with success. The irrigation envelope offers an alternative treatment of value in special cases. Both methods possess advantages over tan treatments: first, infection can always be limited and never develops to the same extent as often happens under an area of tan; secondly, the splinting effect of tan, with its harmful effects on the immobilized joints, is avoided. Nevertheless, in widespread burns of the trunk tanning methods may save life in the early stages.

Our thanks are due to Dr. R. D. Clay, who was responsible for all the bacteriological investigations.

TREATMENT OF BURNS BY ENVELOPE IRRIGATION

BY

JOHN W. HANNAY, F.R.C.S.Ed.

Surgeon, E.M.S.

While no single method for the local treatment of burns has been found universally satisfactory and acceptable, the technique described by Bunyan (1940) of sealing the affected part in a coated silk envelope and irrigating with electrolytic sodium hypochlorite merits a thorough and critical trial. In the past six months 16 cases have been treated by this means at the London Hospital and 8 by other methods. Two were caused by electricity; the rest were due to the commoner agents encountered in civil practice and to wartime incendiary bombs. When the burns were multiple, as was often the case, different methods were used on the separate lesions and comparisons made between them.

The two main problems in the local treatment of any burn are the prevention of infection and the prevention of pain. The latter is largely a matter of controlling the former. If infection is prevented a superficial burn will heal satisfactorily by any method and a deep burn will be the sooner ready for the essential skin graft. Though descriptions of cases and their treatment glibly describe the degree of a burn, I have only once seen mentioned the difficulty presented by this assessment (Mowlem, 1941). It is often impossible to decide on the depth of injury at different sites of the lesion for several days, when it is frequently seen that original estimates were incorrect.

In general, large superficial areas heal more slowly than small deep ones, and the time required for the last few areas to heal, especially over the dorsum of finger-joints, is most tiresome. Many cases after a time advance extremely slowly, and a change of treatment is required to hasten progress. Healing is usually most rapid on the face, less so on the upper extremity, less still on the lower extremity, and slowest of all on the dependent flexor aspects, notably behind the knee. It is more rapid in the young than in the old, and in women's faces than in men's, where the growth of beard may lead to considerable discomfort and delay. It is particularly necessary to shave the scalp if forehead lesions are anywhere near the hair margin. The only delayed healing of a face burn was due to this omission.

Theatre toilet, though universally accepted in principle as essential, seems to be regarded as of less importance in practice; especially is this so in burns of moderate degree and extent, which are treated in out-patient departments. This is a great mistake, for one night spent in hospital following an efficient cleansing under anaesthesia may save many visits later as an out-patient. A stoker with burns of face and hand caused by his furnace "blowing back" was treated as an in-patient with no theatre toilet. A few days after he left hospital his substitute was admitted with almost identical burns from the same faulty furnace. With similar treatment, following cleansing under anaesthesia, he left hospital healed in two-thirds of the time.

Lastly, how does one honestly maintain "full aseptic precautions" in cleaning up a burn in the theatre, especially an air-raid casualty?

Technique of Bunyan - Stannard Envelope Method

The principle consists in enclosing the affected part in a transparent coated silk envelope, irrigating with electrolytic sodium hypochlorite three times daily through vents provided, and using the envelope* as the only dressing between irrigations.

* These envelopes, made for different parts of the body in a variety of shapes and sizes, may be obtained from William Stannard & Co., Leek, Staffs.

Numerous modifications and improvements have been made since the method was first used to overcome various difficulties as they arose. A case of burns of the hand, wrist, and forearm is now treated in this hospital as follows:

When any necessary treatment for shock has been given the patient is anaesthetized in the theatre. An assistant first washes and swabs away loose debris with normal saline and rests the limb on a sterile towel. The surgeon, prepared as for an operation, "with full aseptic precautions," next cuts away with scissors any blistered areas and removes with forceps such injured tissue as can be removed with a minimum of force. No scrubbing is employed, as it adds further trauma to already damaged tissues. The limb is then suspended freely over a bucket and hosed or syringed with a 20% solution in tap-water of "milton" at 105° F. for 10 to 15 minutes, until thoroughly clean.* A suitable-sized envelope is then drawn over the limb, and the upper open end sealed well above the limit of the lesion by two overlapping turns of special webbed adhesive strapping. Variban has been substituted here when the recommended strapping was unavailable, but is less satisfactory. The patient is then returned to the ward.

About six hours later the first irrigation is given in the ward. The limb is supported on a mackintosh pillow so that the elbow is higher than the hand. The lowest vent of the envelope is doubled over on itself and closed with a special clip. As a substitute a spring-backed paper-clip with edges guarded by slit rubber tubing works admirably. For added security to the seal a rubber ribbon is tied firmly around the envelope just distal to the strapping. From a large container with delivery tube and glass nozzle, 2½% milton—i.e., 1½ oz. milton to 1 pint of tap water—at 105° F. is directed through the upper vent into the envelope and over the lesion. When the envelope is sufficiently filled to cover the lesion completely the upper vent is doubled over and clipped. The patient is then encouraged to move his fingers and wrist in the fluid for three to five minutes, before the fluid is drained into a bucket by releasing the lower clip. The process is now repeated once, and the complete performance takes about twenty minutes. After the second emptying the rubber ribbon is untied and the limb must hang down, with all vents open, to drain for twenty minutes. The process is repeated the following morning with 2½%, but thereafter 5% milton is used thrice daily.

Provided a rubber ribbon is tied below the seal during irrigation to take the hydraulic pressure, the more elaborate methods of sealing first used are quite unnecessary. In one case no seal at all was employed, the envelope being held in place between irrigations by a piece of tape tied around the limb, and this proved both satisfactory and comfortable.

For the first case treated here—in a home-made envelope which leaked—normal saline was used. Considerable oedema persisted, and the burn and surrounding healthy tissue became increasingly macerated. After a week milton was substituted, and the oedema disappeared in two days. The maceration followed less rapidly.

This maceration did develop, however, especially of the cornified palms of labourers, in subsequent cases when using milton. It is now almost completely overcome by adequate postural drainage after each irrigation and by leaving all vents open between-whiles. Although this latter theoretically admits secondary infection, which the envelope method was designed to occlude, in practice it does not seem to occur. If a tendency to maceration is still found, resting the limb on hot-water bottles to increase evaporation will almost certainly overcome it. This has not been necessary here since the early cases. The distension of the envelope with oxygen after each irrigation to prevent maceration was suggested, but it did not seem to be of any value, and, in any case, attention to drainage is all that is usually required.

If the lesion is thoroughly hosed with 20% solution at the initial cleansing a degree of anaesthesia appears to be produced. After the first early morning one, using 2½%, subsequent irrigations with 5% do not give rise to any complaints. Though a few say it stings—and this stinging

* Milton is an electrolytically prepared solution of sodium hypochlorite, stabilized at 1%.

sometimes begins even half an hour after irrigation—the majority of patients welcome the procedure as painless and comforting.

An electrolytically prepared hypochlorite was chosen, as saline remains after the liberation of its nascent chlorine; whereas chemically prepared varieties, such as eusol or Dakin's solution, have more irritant end-products. Milton was thus used, as it filled requirements, and was supplied to hospitals at the special price of 3s. 6d. to 5s. a gallon, according to quantity. However, since the first few cases, when Milton was used, the hypochlorite employed has been prepared electrolytically in the hospital dispensary. With an apparatus made entirely by the chief dispenser, Mr. C. H. Sykes, a 1% solution of electrolytic sodium hypochlorite is prepared by switching on the current and switching it off when a bell rings. This has been found to remain completely stable after six months, and is diluted in the theatre or ward to the strength required. The cost is about 6d. a gallon. The only further essential is the non-interference by enemy action with the electric supply.

The initial disadvantage of leakage and wetting of the bed through an imperfect seal has disappeared since using a rubber ribbon; but, at seams especially, and also by permeation through the envelope, a certain amount of fluid still gets through. In a "good" envelope this may not start for nearly three weeks, but sometimes it begins as early as the fifth day. It is quite controllable by a mackintosh sheet under the part, but when the fault is eliminated by technical improvement in manufacture the method becomes entirely free from "mess"—except perhaps in the theatre at the initial cleaning. (I believe this difficulty, due mainly to delay in obtaining materials, has now been overcome.)

When filling an envelope enclosing a leg, the lower part is bellied out by the entering fluid, which draws the upper part painfully tight across the limb until raised off it by the envelope's becoming completely filled. If a length of Gooch splinting is placed beneath the limb and the free edges are drawn up on either side and suspended from a bed cradle, a trough is formed outside the envelope which prevents this.

With an extensive deep burn, progress becomes delayed after a time—as with many chronic conditions. This time of delay presumably varies with individuals; sufficient long-standing cases, however, have not been treated to do more than suggest that, with the envelope method, the first four to six weeks is the period of most rapid improvement. If, when envelopes are changed on account of leaking, the lesion is again hosed down with 20% solution, healing appears to be accelerated.

Only limb burns have been treated here by this method, though a case is still being awaited which can be enclosed in an envelope extending from breasts to mid-thighs and allowing easy use of a bed-pan by an ingenious gusset. It has so far only been successfully fitted and filled on an uncomplaining student.

A few cases of infection have been treated, but these are not discussed in this paper.

— Comment on the Method

Infection.—As bacteriological controls here have been so incomplete, the subject of infection can only be discussed clinically—i.e., when granulations are pale pink and no pus is present, infection is assumed to have subsided or not to have occurred, as the case may be; though cultures from the surface would almost certainly show organisms. In not a single case treated from the onset by the envelope method has severe infection occurred. With a theatre toilet it has been subclinical; without this cleansing it was only slight, and rapidly subsided. This is a very

important advantage; for whereas with any other method preliminary cleansing in the theatre is essential, with an envelope the healing time is not so disastrously prolonged if this still highly desirable cleansing has to be omitted. And in certain circumstances this omission may be inevitable. Where infection is already present an envelope is the most satisfactory method of cleansing. Repeated dressings of any nature should be done not less often than two-hourly—which is very time-consuming, and is disturbing to the patient—or they stick, and their removal is painful and destructive. This can be avoided by covering with tulle gras; but cleansing is then very much delayed, as the gaps in the mesh soon became blocked by exudate. Hypochlorite compresses clean more rapidly than saline, which produces maceration by the tenth day at the latest. This is the great disadvantage of the saline bath. The envelope sticks not at all or very slightly, is the least painful method, thrice-daily irrigations are adequate, and progress can easily be watched without disturbing the lesion or the patient.

Pain.—This is virtually absent. After the first early morning irrigation patients seldom mention more than a slight stinging. This is rather the exception, and has not persisted for more than a day or two. In three cases in which both hands were burnt, one was treated with an envelope, the other by ointment dressings—and in each instance preference was volunteered for the envelope.

A patient treated by Mr. Alan Perry had the whole of his hand coagulated by a severe electric burn. It was enclosed in an envelope and irrigated for thirteen weeks, four envelopes in all being used. During this time part of the palm and all the digits except the little finger sloughed away, but after the first few days there was no complaint of pain or any sign of secondary haemorrhage.

A girl aged 16, whose nerve had completely gone following burns of both lower limbs from thighs to feet, was treated by triple dye jelly. Despite initial theatre cleansing, one leg and then the other became infected, and although this was suspected—even leading to re-examination under anaesthesia on the fourth day, when no pus was found—it was not until the ninth day that the pellicle showed definite signs of infection beneath. From then onwards the whole areas of both legs became infected. One was treated in an envelope, the other with Milton compresses over tulle gras. The patient became almost unmanageable, and begged for the second leg to be enveloped. After this had been done she settled down in a few days, and took the greatest interest in watching the progress of her condition through the transparent envelopes.

There is no doubt that patients have preferred the envelope to any other method used on them—though, with a number in a ward at once, mass suggestion certainly plays a part. The only real complaints have been of soreness from the strapping seal.

Use.—This is a further great advantage in treating hands. From the second day they can be used, painlessly, for coarse movements through the envelope, such as feeding, holding a book, or doing the hair. For superficial burns of the hands no movement should be lost. For deeper burns the patient continues to move the hand while waiting for sloughs to separate—at first only in the fluid, but in a few days at all times. Where loss of tissue—e.g., tendons—means inevitable impairment, movement of course suffers; but otherwise, movement never having been lost, the tedious process of regaining it does not arise. The only disadvantage of using the hands too enthusiastically would appear to be the earlier leaking of the envelope.

Nursing.—The staff are saved a great deal of time if several cases are being treated by the envelope method. One preparation does for all, and there is no scrubbing up between cases. While one patient is moving the fluid over his lesion the envelope of the next is being filled. With a solitary case, rather less time and preparation are involved in "dressing" the burn.

Cost.—This depends on the size of the area to be treated, as the larger this is the larger the envelope and the more solution required. For an arm, however, the hypochlorite as prepared in our hospital dispensary would cost 3½d. a day. To that is added the cost of the envelopes: no other dressings are required.

Analysis

The 24 cases involved 51 areas; these were treated as follows:

(a) *Ointment dressings* were used only for clean burns. If an area of infection developed it was quickly controlled by compresses, before it became deep or extensive. All faces except one were dealt with by this method, and 14 cases in all.

(b) *Saline Compresses.*—This method was used in 8 cases, one of which, a burnt face, healed satisfactorily in nine days. In all the others it had to be abandoned, as maceration became too marked. The method is, however, useful for a few days to clear up a limited area of infection.

(c) *Electrolytic sodium hypochlorite compresses* in solutions varying from 5 to 50% were found more effective than saline in treating infected areas, of which 7 were encountered.

(d) *Flavine in paraffin* was used in only 3 cases. It appears to have little advantage over ointment for a clean burn, and is more messy.

(e) *Triple dye jelly* was applied to 6 areas after careful cleansing under anaesthesia. In every single case almost the whole area covered became infected, superficial burns became deep, and weeks were required to heal. One needed a skin graft and another may do so. Even if perfect healing had occurred, the method was messy.

(f) *Envelope Irrigation.*—This was employed on 13 burns from the start and on 8 after infection had supervened.

Summary and Conclusions

Treatment of burns by envelope irrigation with electrolytic sodium hypochlorite has been tried in 16 cases, and the results are compared with those in 8 cases treated by other methods.

When thorough surgical technique is impossible the envelope method will minimize the dangers of infection; and when infection is already present no other method will clean the wound so rapidly or so effectively. By its use treatment is almost painless—an advantage especially noticeable in infected cases. The method is cheap and convenient, making nursing simple.

Other methods will heal a burn or bring it to the stage of grafting within comparable degrees of time, attention, and discomfort, provided all goes well. The great value of envelope irrigation is that one can be quite certain that in no case treated by it, with or without theatre cleansing, will anything more than mild infection occur. Can this be claimed for any other method?

I should like to thank Mr. Neligan, Mr. Perry, and Mr. Dix for permission to publish these cases, and to record my appreciation of the enthusiasm shown by the nursing staff despite early difficulties.

The Biochemical Society would like to give any possible assistance to foreign visitors to this country who are interested in biochemistry. The following notice, published in the last programme of the Society, may be of interest: "On behalf of the Society the Committee wish to extend a cordial invitation to biochemists and others interested in biochemistry, from the British Empire and countries abroad, to attend meetings and to take part in the discussion of papers. If such visitors wish to receive programmes of the meetings and advance abstracts of papers, they should send their names and addresses to the Secretaries." The Secretaries of the Biochemical Society are: Dr. F. G. Young, National Institute for Medical Research, London, N.W.3, and Dr. W. T. J. Morgan, Lister Institute of Preventive Medicine, Chelsea Bridge Road, S.W.1.

MUMPS MENINGO-ENCEPHALITIS

BY

A. W. FRANKLAND, B.M., B.Ch.

Captain, R.A.M.C.

In a recent epidemic of mumps among soldiers 234 cases were treated in hospital. For the most part only the more severe cases were seen, the milder ones obtaining treatment in their own camps. In a mumps epidemic with meningeal symptoms, coming as it did at the end of a severe epidemic of meningococcal meningitis, it was not surprising that quite a few patients with mumps were sent into hospital with meningitis as the tentative diagnosis. In only 5 of these cases were the symptoms severe enough to justify lumbar puncture. In all these cases a pleocytosis was obtained in the cerebrospinal fluid. Many more cases were sent in for lumbar puncture, but the diagnosis rested largely on the recognition that such a symptom can occur. It was soon apparent that it was not necessary to have either parotitis or orchitis: the meningeal symptoms in contact cases of mumps could be presumed to be due to the mumps infection.

That meningeal involvement occurred fairly often in a mumps epidemic has been known since the middle of the eighteenth century, but it was not until 1902 that Monod described the findings in the cerebrospinal fluid. Gordon (1913) was able to produce an encephalitis in a monkey by intraspinal injections of saliva filtrates. Both Birnberg (1939) and Silver (1936) suggest that the frequency of symptoms from the central nervous system varies from epidemic to epidemic. Pleocytosis in the cerebrospinal fluid may or may not produce meningeal symptoms. It is stated that there is an increase in cells in the cerebrospinal fluid in 50% of cases of mumps, though some authors put the figure as low as 0.1%.

Table showing Illustrative Cases

Case No.	Age	Presenting Symptom	C.S.F. Cell Types	Cells per c.mm.	Complication	Days after Onset
1	26	Parotitis	Small mononuclear; occasional large mononuclear	230	None	—
2	35	Meningitis	All lymphocytes	375	Parotitis	1
3	35	Submaxillary swelling	"	525	Orchitis	6
4	32	Meningitis	Lymphocytes; occasional endothelial cell	1,078	None	—
5	22	"	All lymphocytes	928	Orchitis	11

No organisms were seen in any of these cases, and the cultures remained sterile. In two the C.S.F. pressure was raised, but both patients were very excited; the other cases were within normal limits of pressure. In Case 2 the fluid was not quite clear, while in Case 4 the fluid was definitely opalescent. In Case 5 no parotid swelling was seen, though a severe unilateral orchitis developed eleven days after the onset of meningeal symptoms.

If parotitis had been present the symptoms of a meningeal involvement were fairly easy to recognize. The onset varied from the first to the fourteenth day, though commonly it occurred about the fourth or fifth day. Headache, with a pyrexia generally over 100° and quite often over 102°, appeared, ushered in by nausea and vomiting. Some degree of neck rigidity was a constant finding, the patients complaining of pain in the head, neck, and back. In two of the cases head retraction was present. Bradycardia, Kernig's sign, and photophobia completed the picture of a meningeal reaction. The temperature, vomiting, and headache generally began to subside on the third day. Most patients were free from any symptoms except weakness soon after the fifth day. One patient, who was in hospital for a month, still complained of head-

ache in the mornings. He fainted the day after discharge and was readmitted with no abnormal signs but symptoms of headache and depression. After a period of three weeks' convalescence he seemed to be well again.

Treatment

It was only natural to give sulphapyridine to cases showing meningeal symptoms. If the cerebrospinal fluid is not clear there can be little justification for withholding a drug which may be life-saving. Only the first three cases in which the fluid was not clear received the drug, 9, 8, and 6 grammes being given in the twenty-four hours. Vomiting, headache, and depression were made worse and recovery was delayed. Certainly those patients not receiving sulphapyridine recovered more quickly. Eventually treatment was mainly symptomatic—aspirin and phenacetin, with copious glucose and fruit drinks. A wash-out of the stomach on the third day with bicarbonate and an enema seemed to give much relief.

Comments

Mumps is a virus infection probably spreading via the blood stream and therefore able to affect any part of the body, with a predilection for the parotid gland. In the epidemic described the number of cases of mumps with complications was high. The percentage of all cases of patients developing meningeal symptoms in the epidemic was difficult to judge, but of those admitted to hospital 30% had signs and symptoms of meningeal involvement. It is possible that the particular virus was of a neurotrophic type. The meningeal symptoms have been described as due to the parotid gland compressing the internal jugular vein. This can be discounted because not all cases have a parotitis. In the cases described no polymorphonuclear leucocytes were seen in the cerebrospinal fluid; it is therefore to be expected that sulphonamides will not alter the course of the disease. A guinea-pig received some of the cerebrospinal fluid from Case 5 intracerebrally: no rise of temperature and no apparent ill effects ensued.

TREATMENT OF IMPOTENCE: A COITUS-TRAINING APPARATUS

BY

J. LOEWENSTEIN, M.D.

For the purpose of this paper I understand by impotence solely the impotentia coendi caused by disorders of erection, accompanied, nevertheless, by normal ejaculation and normal orgasm. This is the most common form of impotence. The greater number of these cases are psychologically determined. The much rarer cases of organic impotence are not taken into consideration here, although they, too, are sometimes partially determined or accompanied by psychological factors. The treatment of psychological impotence is of course mainly a psychological one. It is carried out by the usual methods of persuasion, suggestion, and analytical treatment. Sometimes physical, medicinal, or hormone therapy is applied in addition, but all these methods are efficacious mainly through influence on the mind. In the same way, treatment by a training apparatus (according to Dr. Spiegel) which will be discussed below displays its therapeutic efficiency only through its effect on the mind and will.

This apparatus aims at supporting the insufficiently erected penis at its immissio. Accordingly, it is only a mechanical expedient without any therapeutic value of its

own. It gains this value only when its application is organically fitted into the framework of an individual psychological treatment.

Psychological Impotence

Psychological impotence consists essentially in inhibitions which hamper the normal process of erection in the spinal cord so that the erection necessary for the immissio fails to occur. These inhibitions mostly consist either of conscious ideas or of unconscious and suppressed complexes and conflicts, the nature of which is disclosed by analytical treatment. But common to all cases are the fear of the failure of erection and the associated idea: "I am impotent." The erection is essentially a psychological process, and no other process is so liable to be disturbed by inhibiting ideas as that of erection, particularly in neurotic individuals. The bare idea of failure and the ensuing self-observation may be of such a strong inhibiting nature that erection fails to occur. Each new fiasco will enhance the autosuggestion: "I am impotent." In mild fresh cases without parathatic superstructure this inhibiting autosuggestion may be overcome by a reassuring explanation alone. In more serious and inveterate cases the impairing basic complexes and conflicts have to be made conscious and resolved by analytical work. If this is attained to a sufficient degree, not only are the original inhibitions removed but, as a rule, also the idea of insufficiency, together with their autosuggestive consequences, so that normal erection will take place.

Sometimes, however, there happen to be cases which take quite a different course. In spite of good results of the analytical treatment, the patient fails again in an attempt to cohabit, because the habitual self-observation and mental tension hinder erection. Such renewed failure will, of course, further enhance the autosuggestion of incurable impotence and will not only nullify the past psychotherapeutic treatment but even endanger any future attempt. There will scarcely be a psychotherapist who has not experienced such disappointments while treating cases of impotence.

The Apparatus in Use

In order to overcome this embarrassment a coitus-training apparatus has proved to be very efficacious. It consists of twin splints made of thin wire which support the underside of the membrum, ending at each end in a ring. The ring at the pubal end rests upon the symphysis, while the opposite one grips the sulcus glandis, so that the glans remains beyond. In order to adjust it there are hinges at the upper side of the rings. The apparatus is to be fixed to the flaccid penis, and this takes no more time and trouble than, for example, putting on a condom. The two splints are held together at the pubal end by a small rubber ring, which makes it possible for the apparatus to adapt itself to all changes in the circumference of the penis. It is extremely light and easy to handle, and it does not hurt or irritate the male or female partner. Besides, it is so inconspicuous that the female partner does not necessarily notice it. The photograph, reproduced half-size, demonstrates this apparatus.

When the psychological treatment of a case is drawing to its close and the psychotherapist has gained the impression that the erection proper will function but, on the other hand, is afraid of interference caused by autosuggestive influences, the patient is handed the apparatus with the necessary instructions. The conviction is imparted to him that with the help of the apparatus he will be able at any time, regardless of erection, to accomplish a coitus, and that a failure is excluded. It is very likely that the patient will soon report a perfect success. Either the erection of the supported penis was in itself vigorous enough, so that the patient was able to accomplish the

cohabitation unperturbed by the apparatus, or the erection was imperfect, which, however, did not prevent insertion of the flaccid membrum into the vagina and accomplishing the cohabitation. In either case the patient is to be advised to use the apparatus for some time, in order to give him a sense of absolute security and to prevent a recurrence.

After a training of several weeks the patient's self-confidence will become so strong that he can dispense with the apparatus for good. (For want of space it is not possible to report case histories. Yet it may be mentioned that this paper is based upon the results of 36 cases.)

It is necessary to stress the point that the patient must not receive the apparatus before the psychological treatment is finished. Application of the apparatus at any earlier stage would not only impair the effect but endanger recovery, because the unsolved complexes would still retain their hampering influence on the reflexes. It stands to reason that the apparatus cannot replace psychological treatment, and if prescribed indiscriminately it will often be a failure and the last stage of the patient be worse than the first.

A further indication for applying the apparatus may be given by certain cases of homosexuality. One of the dominant features of this disorder is sometimes a fear of being impotent with women. In such cases it is not too difficult to resolve the unconscious complexes and inhibitions and so prepare the soil for heterosexual activity. Yet again the check to erection through the habitual counter-suggestions constitutes an obstacle that may be overcome by the training apparatus.

A final remark may be offered about the impotence of the elderly male. Potency does not usually disappear at once, but gradually. There is a long period of decreasing and changing potency. It is obvious that during this period many opportunities arise for the development of psychological inhibitions. Therefore it is always necessary to inquire for psychological causes when an elderly man complains about a considerable decrease of his potency. Naturally, the first surprising failures, which sooner or later are bound to occur, will lead to the horrifying idea: "Now my potency is gone for good and all." This idea will not easily leave the despairing or resigned man. I need not repeat the further psychological reactions which ensue and render the whole situation more and more hopeless. It is not right—as is often done—to provide the patient with a few consoling phrases about the laws of Nature and then leave him to his own devices. For these are the very cases in which psychological treatment and the prescription of the training apparatus are indicated, sometimes preventing tragic complications.

Of course, failures may occur. Their cause is not always a badly fitting apparatus or awkwardness on the part of the patient. Sometimes, in spite of the apparatus, erections do not reappear. These are the cases in which the most thorough and painstaking analysis fails because

an original inferiority of the sexual organs meets the hampering psychological influences. If this inferiority of the sexual organs is diagnosed previously, the application of the training apparatus is contraindicated as well as treatment of the impotence by any other means.

Summary

In the last phase of the treatment of impotence full success may sometimes fail to appear because the patient's habitual self-observation and counter-suggestion impair erection. In such cases the described coitus-training apparatus is to be recommended in order to complete the psychological treatment. Its application is indicated only within the framework and at the end of a psychotherapeutic cure.

Medical Memoranda

Tetanus Treated with A.T.S., Avertin, and a High-calorie Diet

The following case seems to be interesting enough to merit publication.

CASE REPORT

A male farm hand, aged 22 was admitted to the Hospital of St. Cross, Rugby, on October 5, 1940, suffering from well-developed tetanus. There was a history that six days previously, while returning from church on Sunday morning, he had felt very cold and "could not walk home quick enough to get warm."

The following day his jaws were stiff and he felt "sore in the back." No notice was paid to the symptoms, and he continued at work. On Tuesday his back was more troublesome and his jaws ached, but milking and other duties on the farm were fulfilled as usual. On Wednesday he was persuaded to remain in bed until after the midday meal. He now complained of much stiffness in the back; but in the evening it was still possible for him to stoop down to lace up his boots. Less discomfort was experienced when he was active; consequently he walked about the kitchen to obtain relief. On Thursday there was no improvement, but medical attention was not considered necessary until the following day. Even then the patient described his condition as "not very bad"; he could eat his food and smoke cigarettes, and at night slept well. On Saturday his medical adviser examined him again and made inquiries concerning recent injuries. The patient then recalled stabbing his left small toe with the prong of a fork fourteen days previously. The accident had occurred as he was cleaning up the rick yard. At the time of the injury the boot had been removed, but only a trifling scratch was visible; the wound was thus ignored and forgotten.

On admission to hospital a slight superficial injury to the left small toe was found; risus sardonicus was noticeable; the masseters were contracted, the forehead wrinkled, and the abdominal wall rigid. Sweating was profuse and breathing difficult, and spasms shook the patient, arching the back. The tongue was also bitten. He was put into a small darkened ward by himself. Morphine sulphate grain 1/4 was injected hypodermically and 3,000 units of A.T.S. was given intradermally and intramuscularly. There was no skin reaction, so 160,000 units of A.T.S. was administered intravenously, followed by a full anaesthetic dose of avertin per rectum.

Six hours later 40,000 units of A.T.S. was given intravenously. The following day more avertin was given at 7 a.m. and 5 p.m. The masseters were slightly relaxed and sweating was decreased. The tongue was sore, pain in the back was severe, and muscular contractions were distressing. Fluids were taken hourly.

The following day brought no change: the patient was continually moaning with the pain caused by the contractions, and he was extremely anxious concerning his condition. During the night 4 drachms of paraldehyde with 6 oz. of water had been given to promote sleep, but a full anaesthetic dose of avertin was necessary early the following morning. All through the day spasms occurred irregularly and the patient was extremely restless, attempting to roll out of bed.

50,000 units of A.T.S. was given. A dose of paraldehyde was necessary at midday and avertin at night.

On the fifth day after admission to hospital spasms were less severe and more infrequent. Food was being well taken until evening, when spasms became frequent and intense. The patient complained of pain at the right angle of the jaw. A dose of avertin at night brought two hours' sleep, so 4 drachms of paraldehyde was given at 3 a.m. The condition of the patient was worse and spasms were still causing distress, consequently 20,000 units of A.T.S. was injected round the site of the injury and intramuscularly, and 60,000 units intravenously. A further dose of avertin caused some relaxation. Only slight improvement was noticeable the following day, and a dose of avertin was necessary to prevent restlessness at night.

There was improvement in the general condition the next day and avertin was not necessary as a sedative; muscular spasms were slight and caused no pain. The patient now made an uninterrupted recovery and was discharged on October 24.

During treatment nursing attention was paid to pressure points and an airway was placed between the teeth to prevent the tongue being bitten. Between spasms the patient could take food naturally. Egg and milk, glucose orangeade, egg custard and cream, with nourishing beverages, were given *ad lib.* One drachm of potassium bromide was given daily throughout.

My thanks are due to Dr. J. W. Wheeler for permission to publish this case.

F. R. BRENNER-SMITH, M.B., Ch.B.

A Case of Double Tubal Gestation

The following case is rare enough to merit being placed on record:

CASE REPORT

The patient, a 4-para aged 30, was admitted to Maryfield Hospital on March 18, 1940. All her previous labours had been without complication. On admission she had vaginal bleeding which began on February 9. Her two previous periods had been normally spaced, but for the five or six months before then they had been coming on every three weeks. She complained of pelvic pain between the periods, the pain being accentuated with the onset of the flow. On March 20 she was examined under a general anaesthetic, and swellings were felt in the lateral fornices. The uterine cavity measured 3½ inches. Curettage was done, and the scrapings were sent for pathological examination. The report received was as follows: "The rather atrophic endometrium shows no evidence of decidual change. Small polypoid growths are present on the surface, and in the interstitial tissue plasma cells are present in fair numbers, indicating a degree of endometritis."

On March 20 the abdomen was opened: some free blood was found in the peritoneal cavity; both Fallopian tubes were distended and markedly pathological, and both were removed. We received the following pathological report: "This is a case of double tubal pregnancy. The larger Fallopian tube contains a gestation sac within which is a foetus of about the seventh or eighth week. The smaller tube is filled with a mass of blood clot in which chorionic villi are present. The embryo was not found. The appearances of this tube are those of a tubal mole." The right tube was the larger one and contained the foetus.

Various textbook writers mention the occurrence of intra-uterine and extra-uterine pregnancy at the same time, of multiple pregnancy in one tube, and of coincident pregnancy in both tubes. Also there may be a consecutive tubal pregnancy in the same patient. Eden and Lockyer state in their *Textbook of Gynaecology* that simultaneous binovular tubal pregnancy is the rarest form of all. They say that up to 1927 at least 42 authentic cases of ovarian pregnancy had been collected, while they had found only 28 cases of proved simultaneous pregnancy in both Fallopian tubes. They also refer to a particularly interesting case seen by Treub of Amsterdam who found quintuplets in one tubal gestation sac.

BACTERIOLOGY

General Bacteriology. By D. B. Swingle, Professor of Bacteriology and Dean of the Division of Science, Montana State College. (Pp. 313. 16s. net.) London: Chapman and Hall. 1941.

Of recent years a succession of textbooks has been published in the United States which deal with bacteriology as an independent science, and with its medical as only one of several important applications. Such a work is *General Bacteriology* by Prof. D. B. Swingle, who deplores, as other authors have, the manner in which the subject is usually taught to medical students. The average course in medical bacteriology is in fact confined to the study of pathogenic bacteria only, to those characters by which they can most readily be recognized, and to such aspects of their behaviour as bear on the phenomena of infection. It would of course be far better to approach the subject in the first instance as a pure science, to present a general instead of a particularized view of what bacteria are and what they do, before dealing with the special characters of pathogens. It need scarcely be said that what stands in the way of such an approach is not so much a wrong attitude on the part of teachers as the lack of time in an already overcrowded curriculum. Another factor is the disinclination of students to revert to long hours of laboratory work having no direct application to medicine, when clinical work has captured their interest, and qualification and practice are their only goal. If the subject is to be taught in this way it should be done in the first year, as a part of instruction in biology; the teacher of medical bacteriology in the clinical years would then find a foundation on which to build. If such a reform ever comes about such a book as this would suit the first-year student. It deals successively with classification, morphology, and bacterial metabolism in a general way, and then gives some indication of the functions or other importance of bacteria in various environments—air, soil, water, sewage, foods, and industrial processes. The few final chapters on pathogenic bacteria and the phenomena of infection are too rudimentary for the student of medicine and in places actually misleading, as in the brief description of a tuberculous lesion, which is said to be an example of "hypertrophy."

The book is profusely illustrated, particularly with line drawings, some of which are over-simplified. Each chapter concludes with a series of "review questions," often of disarming simplicity and rather obvious or redundant; the prize for these qualities goes to "What is meant by 'bacterial flora'?" and "In what ways are human excreta more objectionable than soil?"

MEDICAL ASPECTS OF BOXING

The Medical Aspects of Boxing. By Ernst Jokl, M.D. (Pp. 251; illustrated. No price given.) Pretoria: J. L. Van Schaik, Ltd. 1941.

"Pushing the thumb into the lateral region of the neck is a well-known rough-house trick with which the average clinician is naturally not too well acquainted." So states Dr. Jokl, the author of this fascinating book, which contains a very great deal with which the average clinician is not acquainted. This single quotation may give some idea of why the textbook may be claimed to be unique of its kind. Dr. Jokl has already contributed much to our knowledge of sports injuries, and between 1930 and 1933, in collaboration with Dr. E. Guttman, carried out what was probably the first comprehensive investigation of the neuropsychological aspects peculiar to the injuries

resulting from boxing. His interest in boxing has, to say the least, been keen: he has attended a great many fights, examined hundreds of boxers, interviewed fighters and trainers, been present at necropsies on those killed in the ring, and studied the, as yet, not very large literature, of which a good bibliography is given at the back of this volume. If as a result of his observations he reaches the conclusion that the dangers of boxing are such that its introduction and establishment in educational institutions are to be condemned, that it is the essence of brutality and a dangerous and undesirable form of physical education in which head injuries are unavoidable and may lead to sudden death, dementia pugilistica (punch drunkenness), or other serious complications, he at least sustains his thesis by an overwhelming collection of carefully sifted evidence. The knock-out blow delivered to the chin, which suddenly renders a well-trained athlete a quivering mass of unstrung flesh whose weight alone determines its attitude and position in space, has always fascinated the inquiring mind. The mechanism of this and its possible causes are here fully discussed and make interesting reading.

Throughout the text the author is to be congratulated on a minimal use of technical terms, so that with but little reference to a medical dictionary the non-medical reader, interested in sport, may obtain much information. At the same time it must not be considered that it is by any means a superficial and lightly presented compilation. The clinical, physiological, and pathological questions of boxing injuries are discussed fully and well, and an idea of the wide scope of the author's observations may be gathered from some of the section headings—for example, "physiology of concussion," "solar plexus knock-out," "groggy boxers," "Can a boxer increase his resistance power towards head punches by training?" "fatalities in the ring," "punch drunk," and legal aspects. Apart from intracranial effects, the lesions which boxing may produce are many; thus the punching arm may be rendered ineffective by musculo-spiral or ulnar contusion or by direct muscle damage, the kidney may be ruptured or even the duodenum torn across, and these and other injuries are exemplified.

This is a particularly important monograph which should be of value to neurologists, physicians, surgeons, and medical jurists as well as to the large group of persons, both within and outside the medical profession, who are interested in sports injuries.

A DOCTOR'S POT-POURRI

In Search of Complications. The Autobiography of a Doctor. By Eugene de Savitsch, M.D. Foreword by Arthur Krock. (Pp. 362. 12s. 6d. net.) London: Robert Hale Ltd. 1941.

Dr. de Savitsch entitles his autobiography *In Search of Complications*, but in his earlier life complications seem to have been encountered without any searching for them. His description of the Russian revolution as seen through the eyes of a boy of 13 is a tragedy of the fecklessness and reasoning optimism of the White Russians face to face with grim horror. He escaped with his mother through Siberia to a Yokohama interlude of comedy. When the scene changes to San Francisco the drama becomes a roaring farce rivalling the pen of Eric Linklater. But the farce peters out in privations leading to a tuberculosis sanatorium. Then he is given a chance of becoming a laboratory assistant at Colorado University, and displays an unexpected aptitude for research, especially, as might be expected, on tuberculosis. In this way he comes under the influence of Dr. Sewall, who though devoted to research complains that doctors "accept the laboratory as an oracle when all it was meant to be was a test tube," and encouraged our author to become qualified in medicine

while continuing to earn his own living. He is not so shocked by the manners and customs of the dissecting room at Colorado as the reader will be who has not been inured by an experience of the Russian revolution. Sewall advised him to transfer himself to Chicago and work under Prof. Carlson, whose dynamic personality strongly influenced him. We may hope, however, that in the descriptions of Chicago hospital practice he has given rein to his talent for extravaganza. After qualification he worked at the Pasteur Institute (at which he gives some sly digs), and acquired a high opinion of French surgery. Thence to Vienna, the conditions of which city, both medical and social, immediately before the *Anschluss* are graphically described. After a spell of research work, interspersed with big-game shooting, on the Belgian Congo, the force of his first teacher's opinion asserted itself, and he took to ordinary clinical practice. It is good to read his praise of the general practitioner and interesting to note his fear of the control of medicine by the State.

Some of the medical topics are too fully discussed for the general reader and at the same time too elementary and popular for a medical audience. It is curious to learn, by the way, that in Dr. Savitsch's day the freezing microtome was a novelty in Colorado. The swift transitions "from grave to gay, from lively to severe," though a little breath-taking, add to the individuality of this highly entertaining book. Moreover, a man who after such giddy ups and downs can say, "I feel that adversity has paid full dividends," can claim to have achieved a philosophy of life.

Notes on Books

Watts and Co. are publishing a series of sixpenny pamphlets under the general title of "The Thinker's Forum." No. 9, *The Art of Astrology*, by "GEMINI," goes briefly into the origin of this ancient pseudo-science, which began as a genuine effort to explain what was happening in the world and flourished long after mediaeval times. The authors then show with deadly effect how the story of astrology is littered with prophecies gone wrong; and, coming to modern times, they scarify the newspaper proprietors who play down to their readers by publishing horoscopes.

Prescription Writing and Formulary for Dentists, by Dr. RICHARD L. CIPES of New York, is a textbook written for dental students and practitioners to aid them in the writing of dental prescriptions. The volume contains a variety of information of general interest, such as data on the chemical sterilization of surgical implements, statistics on anaesthetic fatalities, etc. The publisher in this country is Henry Kimpton, and the price 20s.

THEODORE F. TUCKER's booklet *Sex Problems and Youth* is published by George Allen and Unwin at 5s. This sermon on sex, as Dr. Harry Roberts says in the foreword, is better than most in that it is quite frank and not prudently sanctimonious; and yet, high-sounding as it is, one has a feeling that it will be more impressive to those who are not in the toils than useful to those who are. It falls back a good deal on deflection and sublimation, both of which happen and are useful to some but not to all. It is a purely masculine treatise written for the male adolescent, and it is here perhaps, like many others of its kind, that it fails in its purpose. The author is never tired of stressing the duality of sex, yet while he says everything about the possible sufferings of the female he does not mention her responsibilities.

The next award of the Rolleston prize, now worth about £100, will be made in Trinity term 1942, and graduates or research students of the University of Oxford or Cambridge who have not been qualified for more than six years or matriculated for more than ten are eligible. The prize is for original research in animal and vegetable morphology, physiology, and pathology, and essays should be sent to the assistant registrar at the University Registry, Oxford, before March 31, 1942.

SATURDAY JULY 12 1941

TREATMENT OF BURNS

Until the outbreak of the present war there was fairly general agreement on the treatment of burns. Coagulation methods were in use in most parts of the world and were accepted as being superior to all previous therapeutic methods. But those happy days are over. The conformity of a few years ago has given place to non-conformity, and the non-conformity is now showing signs of sectarian division. How far is this sectarian outlook likely to be of real value and how far is it justified by the evidence? Until a few years ago there was little serious criticism of the tannic acid method, and much was heard of its virtues. Since the war the position has been reversed and the value of coagulant methods has been questioned. Wartime burns present many problems not met with in civilian life, but it is doubtful whether the sweeping condemnation that has been made of the coagulant methods is fully justified by the facts. The first-aid treatment of burns suffers from confused counsel, and in hospitals there are the several devotees of coagulants, tulle gras, pastes, saline baths, irrigation envelopes, cod-liver oil, and even carron oil. The sectaries speak with dissenting voices. The therapeutic position has been further complicated both by the recent employment of the sulphonamide group of drugs in combination with the other methods of treatment, and by the claims that some of the methods of treatment are not only ideal for burns but are also equally effective for traumatic and infective conditions.

In all this there is a danger that perspective is being lost. We have to remember that the introduction of tannic acid was followed by a considerable fall in mortality. This important fact must not be overlooked, for it suggests that at least the coagulant methods were based on a sound principle and represented a real advance on earlier methods. That principle was the elimination of toxæmia and of suppuration and its complications in a large number of burns. Glover and Sydow¹ have recently reported some instructive statistics in this connexion. In a series of 1,913 cases of burns treated with tannic acid the mortality was 11.3%, while in a series of 1,369 cases treated by other methods the mortality was 24.5%. These workers showed that the chief reduction in mortality occurred after the first twenty-four hours, and also that the early mortality had not been affected by any method of treatment. In their own series of 809 cases treated with tannic acid the mortality was 8.4%, and half of this occurred within the first twenty-four hours. Glover and Sydow, however, carry their argument a step further. They do not agree with Davidson that the coagulum should be left undisturbed, but recommend that between the fifth and the eighth day, when the coagulum shows signs of separating or lifting, the area should be covered

with continuous Dakin's dressings. The wound then becomes a granulating surface which is rapidly covered with epithelium or is ready for grafting. In this way the authors claim that they get the life-saving advantages of the coagulant methods together with the local and functional advantages associated with the early separation of the tan.

In last week's *Journal* there appeared two articles by Bunyan and by Hudson, and in the current issue two by Pearson and others and by Hannay, all dealing primarily with the envelope method of treating burns and wounds. In the development of the envelope method Bunyan and his fellow workers have shown great ingenuity and resourcefulness. But it must not be forgotten that the method was first introduced because of the disasters which sometimes follow the application of coagulant methods to burns of the hands and the face. Bunyan points out that the ideal dressing for a burn is one which can be kept on during the whole period of treatment and preferably without changing; it should be flexible, frictionless, and bland to the tissues; it should if possible be transparent so that progress can be continuously observed; and it should be watertight so that fluids applied to the area will be confined within bounds. Irrigation of the area is carried out by means of electrolytic sodium hypochlorite solutions of strengths varying from 1% to 50%, the strength depending on the actual condition of the wound surface. The hypochlorite solution is oxidizing and chlorinating in its effects, it is non-toxic, it encourages the transudation of serum and cells, and it exerts some bactericidal effect in strengths that are harmless to living tissues. Bunyan has now treated some 200 cases with the envelope irrigation method, but his paper contains no full analysis of these or of the mortality or end-results. It is pointed out that the method is being used in the treatment of septic fingers, infected tendon sheaths, cellulitis, osteomyelitis, varicose and other ulcers, dermatitis, etc. In the case of burns the position is summarized by Hannay as follows: "Other methods will heal a burn or bring it to the stage of grafting within comparable degrees of time, attention, and discomfort provided all goes well. The great value of envelope irrigation is that one can be quite certain that in no case treated by it, with or without theatre cleansing, will anything more than mild infection occur. Can this be claimed for any other method?"

The envelope method provides an ingenious means of irrigating many areas of the body; it is comfortable to the patient and avoids the necessity for frequent changes of dressing; it counteracts existing infection and prevents or minimizes secondary infection; and it permits exercise of the burnt member if this is desirable. All of these are of high importance in the treatment of war burns. But the method is still in its early stages, and much more experience will be necessary before it can be proved that it is so much better than other measures as to make it one of general applicability. Mortality rates must be the first criterion of success; the preserving of function must be considered as a secondary aim to the preserving of life—the desideratum is the method of treatment that will do both. It is at least encouraging to find that a number of active workers are bending their minds to the problem, and those who serve must in the meanwhile wait until the evidence has been sifted by controlled observation. The War

Wounds Committee of the Medical Research Council some time ago appointed a Co-ordinating Team on Burns; it has not been idle, and in due course we may hope that enough facts will be assembled for accurate inductions to be made.

LACTATION

Recent years have witnessed rapid and important developments in our knowledge and control of the phenomena of lactation of animals, but no corresponding advance can so far be claimed on the clinical side. The clinician may well derive some benefit and guidance from a study of modern experimental work. This is no easy matter, as the volume is truly immense and the subject complicated and often controversial. The available information has been ably weighed up by Folley in a review¹ which has the freshness of first-hand knowledge. With its help the modern concepts of lactational physiology may be summed up as follows.

The suitable development of the mammary gland is the first step in the chain of physiological processes which culminates in the ejection of milk. This growth of the gland is under hormonal control, and it has been found that in most animal species complete development of duct and alveolar systems results from simultaneous treatment with oestrogens and progesterone. There has been much speculation whether this action is direct or mediated by the pituitary. The latter view is supported by Turner's school, which believes that the hormonal stimulus acts on the anterior pituitary, and this in turn secretes two "mammogenic" hormones which promote mammary development. The most recent evidence² is at first sight rather against this important hypothesis. There is hardly any doubt, however, that the anterior pituitary plays a key part in milk secretion. Recent experiments point strongly to the existence of a specific anterior lobe lactogenic hormone or hormones (generally called "prolactin" in this country) essential for the initiation and maintenance of lactation in animals possessing the necessary mammary development. Anterior pituitary extracts which are lactogenic have also the curious property of causing the growth of the crop gland of the pigeon, and, indeed, the most widely used methods of assay of prolactin are based on this property. It is, however, becoming increasingly doubtful whether the crop-stimulating factor is the sole hormone responsible for the initiation of lactation or for the stimulating of lactation in the already lactating animal.⁴ The clinical implications of these findings are bound to be profound. Clinical results with purified prolactin preparations have so far been conflicting and, on the whole, disappointing; yet the administration of crude anterior pituitary extracts to cows in declining lactation has been attended by conspicuous success and may even prove of economic value. As the potency of the prolactin preparations used clinically was assayed by the pigeon-crop test, the lack of agreement about their value for women is not altogether surprising. Folley and Young point out with reason that a woman whose milk-yield it is desirable to increase is more akin to a cow in waning lactation than to a pigeon. They plead rightly that extracts which it is intended to use clinically should be

assayed for their galactopoietic power in mammals rather than for their ability to stimulate in birds the growth of a structure the secretion of which is not analogous to milk. A fruitful field is open here for the cautious and critical collaboration of the clinician with the research worker.

Other hormones take an active if less dominant part in the secretion of milk. They also affect its composition. In view of the importance of the thyroid in the regulation of metabolism, the effect of thyroxine on lactation is easily understood. In cows in advanced lactation thyroxine treatment causes a notable increase in the milk-yield and fat content and a smaller increase in non-fatty solids; indeed the hormone may be regarded as a true galactagogue. Extracts containing anterior lobe thyrotrophin stimulate also, as would be expected, the secretion of milk by the cow. While large doses of oestrogens are used clinically to inhibit lactation, it may not be generally known that small doses are galactopoietic. In the cow, for example, appreciable increases in the fat and "solids-not-fat" content of the milk are obtained by such treatment. It is probable that this action takes place through the intermediary of the anterior pituitary. Adrenalectomized animals do not lactate, neither does lactation take place in hypophysectomized animals unless prolactin treatment is accompanied by administration of corticosterone or of the adrenotrophic hormone.

Though the mammary gland is not innervated by true secretory fibres, recent work indicates that nervous influences are concerned in lactation to a greater degree than was formerly supposed. The farmer, for one, has never doubted that the cow, the sow, and the ewe can exercise a good deal of control over the flow of their milk, and to him the "holding up of milk" is an established fact. Hammond has reviewed lately the scientific evidence proving that "letting down" of milk is an active nervous reflex excited by stimulation of the teat, which causes a rise in milk pressure and is essential for the efficient emptying of the udder. In addition to this purely nervous effect the tactile stimulation of the nipple in the act of suckling or milking probably also causes another response, partly nervous and partly hormonal, through the anterior pituitary. Hammond's paper was published in a veterinary journal⁵ and may have escaped the attention it deserves from the medical practitioner. Much can be learnt from it about those first principles of maternal emotion common to man and beast, which make woman experience the "draught," and the cow to "let down" her milk.

Few will be surprised by claims⁶ that, besides hormonal and nervous mechanisms, certain specific nutritional factors are essential to the secretion of milk. These recent additions to the long string of confirmed and probable vitamins—vitamins L₁ and L₂, as they have been called—are apparently needed for lactation alone of all bodily functions, and would thus be true lactation vitamins. It may be a relief in these days of rationing to hear that this work has not so far been confirmed,⁷ and that, moreover, fair lactational success has recently been observed in animals receiving highly purified diets supplemented with all known vitamins in the pure state.⁸ The moral of this is that, provided the nursing mother gets enough of the recognized protective foods, especi-

ally milk, greens, and vitamin D, she need not worry about these more remote letters of the alphabet. Milk contains three constituents which are found nowhere else in nature—lactose, caseinogen, and the characteristic milk fat. There has been much speculation as to their origin, and much ingenuity has been displayed in bridging the gap between blood and milk. How this was done is well described by Folley. Those with a biochemical leaning will read with interest this story of scientific detection, and will learn how radio-active elements acted with conspicuous success as blood-hounds. The tale of recent achievement in lactational physiology is truly impressive. It may be fallacious to argue from mice to men, but to apply the results of experiments on mice (and cows) to cautious clinical work is but common sense.

SKIN AND MIND

It has been well said that the skin, like the Freudian ego, faces two ways—inwards towards the body, and outwards towards the external world.¹ For this reason it forms a particularly suitable medium for the study of what have been called "psychosomatic" problems, or the effects on bodily function of emotional disturbances. It is surprising that it has not received more attention from dermatologists and psychiatrists, so that the psychological section of even the most ambitious of dermatological textbooks is not as illuminating as it might be. What should also commend the topic to the "dermatopsychiatrist" is the fact that the skin is unusually susceptible to emotional influences, both directly in the vasomotor and pilomotor reactions, and indirectly through the influence of disturbed gastric function on the skin.² Furthermore, skin reactions are visible to the eye, so that the effects of guilt and pride as inner sources of psychological conflict are intensified. The skin, in fact, becomes a kind of colour indicator of the state of the super-ego, so that it is not so fantastic as it sounds to say that in some cases rosacea may represent the perseveration in a predisposed skin of the operation of a bad conscience. Occasionally, as in some cases of dermatitis artefacta, the skin receives assaults upon it which are dictated by a guilty mind seeking to expiate its naughty wishes. Stokes, more than most dermatologists, has realized the potentialities for clinical and pathological observation that are thus offered, and in his most recent publication he has reviewed the psychosomatic correlations of allergic conditions.³ The remarkable effect of hypnosis in some states of allergic sensitiveness, and its ineffectiveness in others, suggests a mentally rather than physically conditioned basis for some allergic phenomena. It can even be said that the allergic personality (for example, in the child with the eczema-asthma-prurigo complex), which is described by Rogerson⁴ as one of unusual intelligence, ambition, and aggression, has to be understood before the manifestation of allergy in an individual case can be fully comprehended. The frequent association of certain allergic phenomena with a particular type of personality suggests a basis for a theory of temperament, and is also important for practical clinical examination.

These are but examples of the possible relationships of mind and skin. Not only guilt, but anxiety in any form, anger, desire for sympathy or attention or escape, tension and conflict, desire and substitutive satisfaction, can all be reflected in pathological conditions of the skin. Disturbed relationships between parent and child, husband and wife, may all be mirrored there as physical signs, just as they so

often are in psychoneurotic symptoms. The immediate reaction of the essentially physically trained dermatologist to such observations is, as Stokes points out, "apt to begin with confusion and end with incredulity"—a sequence hardly to be marvelled at. Not only dermatologists, but physicians of all branches, would do well to recognize the wisdom of Stokes's admonition "to recognize that other specialties besides his own have their intricate observational criteria as objective and valid as his, and to avoid the role of obstructionist; and so advance the cause by tolerance, even if he cannot supply critical understanding and unqualified acceptance."

CONSANGUINEOUS MARRIAGES

It is now known that any effect upon the children of blood relationship between the parents is simply due to the tendency of relatives to share more of the same kind of genes. A recessive trait is more likely to appear among the children of cousins, because they are more likely to carry the same genes in heterozygous form. This aspect of the problem of consanguineous marriage has received much attention, though actual data have been scarce. In 1934 the Human Genetics Committee of the Medical Research Council decided to obtain the co-operation of hospitals in a large-scale survey. The principal objects were, first, to ascertain the frequency of consanguineous marriages; and, secondly, to discover whether any particular diseases were associated with an increased frequency of such parental relationship, thus indicating the action of recessive hereditary factors (which would have to be rare to produce any marked difference). Dr. Julia Bell has analysed 69,000 completed cards (a further 20,000 were usable for certain purposes only), and the results have recently been published.¹ The brief, though interesting, historical introduction is perhaps misleading in one respect. While it is true that eugenic fears were by no means unknown in the past, the compulsion behind the universal human taboo on incest is sociological, being the need for maintaining a harmonious family group. This is clearly shown in the very able report recently published by a Church of England Commission.² The incidence of first-cousin marriage among the parents of 49,000 in-patients in general hospitals was 0.61%, and a division by age showed that the rate has been declining in recent years. Among the smaller number of out-patients the rate was somewhat higher, and it was notably higher in special hospitals among both in-patients and out-patients with neurological diseases. The findings of a study of the connexion between the consanguinity rate and the occurrence of different diseases are, on such numbers as these, suggestive rather than conclusive. High on the list come steatorrhoea, dystrophia myotonia, congenital dislocation of the hip, muscular dystrophy, talipes in infants, leukaemia, exostoses, dermoids, arthritis, tics, diabetes mellitus (especially in the young), and paralysis agitans. Some of these are undoubtedly hereditary and recessive, and investigation of the others, as well as of some conditions too numerous to be mentioned here, would be a promising line of research. One remarkable finding was that, while cancer taken as a whole showed no undue consanguinity rate, the incidence among patients suffering from cancer of the cervix was 2.19%. Further data were obtained with the help of the Radium Institute of Sheffield and the Marie Curie Hospital in London, when the percentage incidence was found to be 1.74. This figure on the larger numbers—seven first-cousin marriages out of 403—is significantly higher than for the whole hospital

population. It is likely, therefore, that recessive genes play a part in determining susceptibility to cancer at this site. The figures in Dr. Bell's analysis were also used to determine the sex ratio for various diseases. The figures ranged from 86% of males with cancer of the tongue, mouth, and lip to 88% of females with affections of the thyroid gland. These two examples may not be surprising, even though the present generation does not smoke clay pipes, but a number of other figures depart widely from the conventional textbook statements.

THE DYSTROPHIES OF THE MACULA

The classification of inherited lesions of the fundus situated mainly or exclusively in the central area presents considerable difficulties. The ophthalmoscopic appearances and symptomatology vary within very wide limits, but at the same time it is difficult to make a clear subdivision. A long and detailed paper by Arnold Sorsby,¹ containing, moreover, many admirable illustrations, is therefore welcome. The personal observations include a description of members of eight family groups; there is a detailed review of the literature, and something like order is introduced into a complicated subject. There is a genetic discussion, too, and a more general genetic appendix by Hans Grüneberg. In the first place it is shown that the conception of a lesion confined to the central area is too narrow. There may be perimacular involvement and even peripheral lesions. Unfortunately no satisfactory histological evidence is available, and the author states that it is tempting to regard the macular dystrophies as the counterpart of retinitis pigmentosa, the one group of conditions being essentially a degeneration of the cones, the other of the rods. This would account on anatomical grounds for the distribution of the lesions in the macular dystrophies, the changes being most marked in the central region, though not entirely confined to it. In one of the cases described, however, retinitis pigmentosa was present also, and the author prefers to avoid too definite a statement. These retinal degenerations can be separated from two others: central choroidal sclerosis and angioid streaks, which are due to a dystrophy of the central internal limiting membrane. The central retinal dystrophies include a range of ophthalmoscopic appearances varying from fine mottling of the macula to intense pigment formation, hole formation, and exudative reactions. Best's disease, so far reported in one family group only, is not excluded, a notable feature in this instance being almost complete colour-blindness. Another curious condition which must be included is "Doyne's choroiditis." This very rare manifestation is characterized by the massive formation of white dots in the disk-macular area with subsequent atrophy. Haemorrhages and a honeycomb pattern may also be present. The symptoms of macular dystrophy, too, vary widely. There may be, as is well known, almost complete day-blindness, or an affection so slight that the sufferer is himself unaware of it. The condition is "not necessarily rapidly and relentlessly progressive." There is much variation in age of onset also, and some lesions may actually be congenital. The differential diagnosis, apart from the conditions already mentioned, must be made from congenital macular coloboma also. Some non-inherited conditions have to be distinguished: retinitis centralis serosa, traumatic lesions, and central chorio-retinitis. Amaurotic family idiocy presents no difficulty. The single clinical entity, if the author's cogent arguments are accepted, finds no parallel in a single genetic entity. It is certain that more than one main gene may cause the condition, for some cases show dominant inheritance (usually irregular—that is, with skipping of generations), while others are clearly recessive, as is shown

by a high incidence of consanguineous parentage and an absence of affected ancestors. There is no doubt also that the different genes may cause somewhat different manifestations and also tend to operate at different ages.

PREVENTION OF JUVENILE DELINQUENCY

In a normal peacetime year 28,000 boys and girls under seventeen years of age commit indictable offences which bring them before the juvenile courts and, of course, there are innumerable other cases which never come before the courts at all. On June 30 the National Association of Maternity and Child Welfare Centres and the National Association of Probation Officers called a conference in London to discuss the importance of mothercraft teaching as a means of preventing juvenile delinquency. Confronted with the problem of the "difficult" child, an uninstructed mother may very well take the line of least resistance, perhaps encouraged by a neighbour who says that he will "grow out of it," whereas in fact he grows into it, and when he comes to realize that he is not as other children he compensates himself under a sense of inferiority by behaving badly. As one of the principal speakers, a probation officer at Willesden, Miss Kennedy, pointed out, there is a close connexion between bad and unclean habits, and insecurity of environment and child delinquency. Miss Kennedy said that inquiries in reception areas had shown that there were many cases of hitherto normal children who, as soon as they were evacuated, developed bad habits and were moved from billet to billet. When at last they returned home they gave no more trouble—it had not been realized how greatly they had been upset by removal from familiar surroundings. Bad homes are very often responsible for the development of delinquent tendencies; the broken home, the home in which the parents quarrel, parents who fail to adjust their affections as between one child and another, and so forth—all these are factors which directly promote child delinquency. Another factor is failure on the part of the parent to attend to any signs of physical or mental defect in the child. A large number of children who develop delinquent tendencies are not mental defectives but borderline cases, and a child whose defect is merely physical is tempted into delinquency in order to compensate himself. Dr. Leslie Housden, the other principal speaker at the conference, described delinquency as a self-inflicted social disease for which the true remedy had still to be found, the authorities as yet having administered only palliatives without curing the disease. Just as delinquent children were not necessarily mentally defective, so their parents might have no trace of mental defect, and many who reported their children as unmanageable were intelligent people, but, dreaming of the ideal child, they had not seen clearly their own part in the formation of its character. Children, unless they are delicate and weakly, have a store of high spirits and muscular energy, the expenditure of which will be guided by the wise parent: merely to turn the child out of doors to "work it off," made the parent, in Dr. Housden's opinion, an accessory before the fact in the child's probable offences. Too often delinquents are not guided but scolded and abused, and he emphasized the need that parents should realize their responsibility for the creation of a good home atmosphere, which was the chief safeguard against delinquency. Mothercraft consisted of more than merely teaching girls how to feed, clothe, and care for their babies; it also meant their instruction in cleanliness and orderliness. It also taught the supreme importance of the mother's influence on the development of the child's character.

We regret to announce the death on July 8 of Sir William Willcox, consulting physician to St. Mary's Hospital, and for more than twenty years medical adviser to the Home Office.

CHEST SURGERY IN WAR

This is one of a short series of articles based on lectures given at the British Postgraduate Medical School, Hammersmith

SOME ASPECTS OF CLOSED WOUNDS OF THE CHEST

BY

J. G. SCADDING, Major R.A.M.C.

An attempt is here made to consider, necessarily from a main theoretical standpoint, the possible effect of advances in knowledge and technique in the treatment of wounds since the war of 1914-18.

Of such advances three are outstanding. They are: chemotherapy for the control of infection; increased understanding of the technique of artificial pneumothorax; and the development of thoracic surgery, including the elucidation of the principles of drainage of the pleura by closed methods.

Principal Dangers

The chief dangers of wounds of the chest are, in roughly chronological order, mechanical dangers, haemorrhage, and infection.

Mechanical.—Open pneumothorax, due to large gaping wounds in the chest wall through which air freely sucks in and out, or "traumatopnoea," is productive of great respiratory and circulatory distress; the necessity for early surgical intervention in such conditions is obvious. Consideration of these cases is outside the scope of the present discussion; but after surgical treatment of the wounds the thorax will often be closed completely, leaving the patient in a position comparable to that of one whose wounds have been "closed"—that is, not permitting the free ingress and egress of air—from the beginning. Closed pneumothorax, unless of large size and under tension, is not in general productive of distress or respiratory embarrassment: this, of course, is abundantly demonstrated by the large number of patients with therapeutic pneumothoraces, even bilateral ones, who are able to lead active lives. A closed pneumothorax in which the pressures are known and controlled may actually prove to be of benefit in the treatment of certain types of chest wounds. The only sort of pneumothorax without external "sucking" wound which is dangerous to life is that which is under tension because of a valvular pleuro-bronchial communication. This requires active treatment. Experience in 1914-18 showed that such a tension pneumothorax is a relatively rare complication of chest wounds.

Haemorrhage.—This may occur from the lung or from the chest wall. Bleeding from the lung may be into the pleura, giving rise to pneumothorax, generally haemopneumothorax; or into the bronchi, giving rise to haemoptysis of varying grades of severity; or into both pleura and bronchi. In either case this form of bleeding may be controlled more or less completely by collapse of the lung by pneumothorax. Bleeding from the chest wall may be either external, through the exit or entrance wounds, or into the pleura, causing haemothorax. Such bleeding can be controlled only by surgery, since the bleeding vessels—generally intercostals—cannot be compressed satisfactorily by any indirect method.

Infection.—Infection is the immediate cause of the late mortality in chest wounds. Its incidence and nature obviously depend to a large extent on the environmental conditions at the time of wounding. During the war of 1914-

18 conditions were so unfavourable that it is surprising that the incidence of infection was not much higher than that actually observed. The following figures may be quoted:

Open wounds	100	Infected	67 (67%)
Cavities	49	Infected	0
Bullet wounds	33	Infected	6 (18%)
Shell wounds without retained fragments	111	Infected	25 (24%)

Conditions favourable to the development of anaerobic gas-producing infections are provided by the presence of large masses of blood and fibrin clot in the pleura. Hence it is probable that early aspiration of haemothorax may lower the frequency of such infections; and while no statistics are yet available, there can be little doubt that prophylactic chemotherapy by sulphonamide drugs can reduce very considerably the incidence of infections in general. These considerations are important in relation to the question of the maintenance of pneumothorax in chest wounds involving the lung; for if the pleura becomes infected the presence of a large pneumothorax may determine the conversion of what might have been a small localized empyema into a large generalized pyothorax, the gravity of the prognosis and the difficulty of treatment being thereby much increased. Thus if infection is to be expected in from 20 to 40% of cases, as in 1914-18, the maintenance of pneumothorax may well be considered to be more dangerous than useful. On the other hand, if the incidence of infection can be reduced by chemotherapy and early aspiration the maintenance or induction of pneumothorax—the possible benefits of which have been outlined—becomes a matter for serious consideration.

Significance of the Intrapleural Pressure

The measurement of the intrapleural pressure is a very simple matter, and in cases of traumatic pneumothorax much useful information may be derived from it.

Any standard type of artificial pneumothorax apparatus incorporates a manometer with which such a measurement may be made; but if this is not available all that is required is a water manometer connected by rubber tubing to a needle. The manometer may consist of a simple glass U-tube, 30 cm. or more in length, with water standing at rest half-way up each limb: it should be remembered that a change in level in one arm of one unit is equal to a change in pressure of two units, since the change is accompanied by an equal one in the opposite direction in the other limb (Fig. 1). If the needle is by error introduced below fluid, the fluid may be sucked into and out of the rubber tubing; the latter should therefore be sterilized. If it is sterilized by boiling care should be taken that water is shaken out of it as completely as possible, since a small amount of water blocking it will prevent the accurate reading of the intrapleural pressure. Though a special needle is a pleasant luxury any needle of reasonable gauge can be used. About 9 s.w.g. is the smallest practicable gauge, and for simple measurement of the intrapleural pressure in an already existing pneumothorax there is no advantage in using a specially stout-gauge needle. The needle should also be dry; this may be secured by taking it out of spirit and carefully flaming it. To measure the intrapleural pressure in a traumatic pneumothorax a convenient area in an intercostal space above the level of any fluid that may be present should be anaesthetized (though in emergency—e.g., tension pneumothorax—this anaesthetization may be omitted) and the needle inserted through this area into the pleura.

The intrapleural pressure is generally expressed in centimetres of water below and above atmospheric pressure; for convenience the symbols — and + are used to denote these

pressures, though strictly, of course, the term "negative pressure" is nonsensical. Thus $-x$ cm. of water is used to mean x cm. of water below atmospheric pressure. Also, the intrapleural pressure normally becomes more subatmospheric in inspiration and less so in expiration. The mean intrapleural pressure is generally taken as the arithmetical mean of the pressures in inspiration and in expiration. The normal mean intrapleural pressure varies from about -5 to -9 cm. of water.

FIG. 1.—Simple water manometer.

The respiratory excursion of pressure varies greatly with such diverse factors as the depth of respiration and the gauge of the needle; thus with a mean intrapleural pressure of -6 cm. the manometric excursion may be -7 , -5 , or -8 , -4 , or -10 , -2 , etc.

As the size of the pneumothorax increases, the intrapleural pressure also steadily increases, at first becoming less subatmospheric, until in a large pneumothorax it exceeds atmospheric pressure, and in "tension" pneumothoraces mean pressures of $+10$ or $+20$ cm. may be attained. The level of intrapleural pressure at which the pneumothorax causes respiratory distress varies greatly, depending upon such factors as the mobility of the mediastinum and the presence and extent of pleural adhesions; most adults are not distressed with an intrapleural pressure equalling atmospheric, provided it is gradually attained, though with an abnormally mobile mediastinum even -2 cm. may be accompanied by distress. In judging the probable effect of a pneumothorax in contributing to symptoms of distress the measurement of the intrapleural pressure must be correlated with the physical signs, especially the position of the apex beat.

Other pathological conditions besides pneumothorax cause changes in the intrapleural pressure. Of these the most important from the point of view of chest wounds is atelectasis of the lung. Atelectasis causes a diminution in the intrapleural pressure—i.e., the pressure becomes more subatmospheric. The phenomenon is observed even in the presence of a pneumothorax: thus if the pressure in a pneumothorax which has averaged -4 cm. suddenly becomes -10 cm., the most likely explanation is that part of the lung has become atelectatic. Depending upon the mobility of the mediastinum, a contralateral atelectasis will cause a greater or lesser change of similar sort in the pressures in a pneumothorax.

Another variation in intrapleural pressure which is of importance in dealing with older persons is that occurring as a result of pulmonary emphysema. In this condition the normal mean pressure more nearly approaches atmospheric the more severe the changes in the lung. Hence in older men all pressures will be expected to be a little above—i.e., less subatmospheric than—those observed in younger men.

Surgical Intervention

It cannot be doubted that the following three conditions are urgent indications for surgical intervention:

Large External "Sucking" Wounds.—The closure of these is a matter of extreme urgency. As a first-aid measure an air-tight dressing must be applied, and surgical closure as early as possible is indicated.

Extensive External Wounds and Haemorrhage from the Chest Wall.—These are to be treated on the ordinary surgical principles of excision of wounds and control of haemorrhage.

Evidence of a Retained Foreign Body.—The influence of this complication on the incidence of infection has already been noted. Although an immediate recovery may be made without undue delay in cases in which there is a foreign body retained in the lung itself, experience has shown that in a large proportion of these cases chronic pulmonary suppuration—chronic abscess and bronchiectasis—develops subsequently.

Opinion may be divided, however, on the extent of the surgical intervention in these cases, on the application of surgical treatment to cases not showing these indications, and on the relative merits of complete closure of the chest after operation or drainage by a closed method.

With regard to the extent of surgical intervention, this must in practice depend very largely upon the available facilities, both of personnel and of equipment. Without the services of a specialist thoracic surgeon it would certainly seem wisest to confine surgical intervention to thorough attention to the three points mentioned above. In favourable circumstances more complete operations on individual cases and the extension of surgical treatment to suitable cases not showing these urgent indications may prove to be advisable. The extent to which such urgent surgery is likely to be required may be exemplified by the figures of Duval (1918), who was one of the first surgeons to advocate the application of the ordinary principles of wound surgery to chest wounds. He reported that of 161 cases he operated on 46 (29%); 29 (18% of the total) of these were urgent operations for haemorrhage or open thorax, and 17 were later operations for removal of foreign bodies or for "direct treatment of the lung wound." Of the 46 cases operated on 13 ended fatally. 102 cases presented no indication for operation; of these only 1 ended fatally. The statistics were complete, with the exception of deaths occurring at regimental aid posts.

With regard to the question of complete closure of the chest or air-tight (under-water) drainage after operation, the latter has become a routine with many thoracic surgeons for a few days at least after thoracotomy. The advantages of this procedure are that it acts as a safeguard against the development of pressure pneumothorax and that it drains away blood and pleural exudate. The disadvantages are that it often requires much attention for its smooth maintenance, and that it considerably diminishes the ease with which a patient can be moved—a matter that may be of great importance under war conditions. Also, the rapid re-expansion of the lung which a properly arranged under-water drainage secures may be actually disadvantageous if there is a wound of the lung itself; clearly this will tend to heal more readily if the lung remains collapsed for a few days. It need hardly be mentioned that in the presence of a free pleura any form of drainage except air-tight under-water drainage is highly dangerous. On the whole, then, it would seem best, after operative treatment of the limited sort mentioned above, to close the chest completely. This leaves the patient in the same position as regards after-treatment as one with a "closed" wound which has not required operation. Of course, these remarks on drainage do not apply to cases treated in special centres where more radical surgical treatment, even involving lobectomy, may be carried out.

(The article will be concluded in our next issue.)

MOTOR BARGE AS AMBULANCE SHIP

BY

J. EVANS, M.B., B.Ch.

Flight Lieutenant, Royal Air Force Volunteer Reserve

The following description of a motor barge converted to act as an ambulance ship may be of interest. The purpose of the craft is to rescue and evacuate casualties from ships in or around the Thames Estuary.

The craft is a twin-screw coasting barge with two 60 h.p. Diesel engines, having an overall length of 105 ft. with a maximum speed of 8 knots. When it was taken over the accommodation available for conversion consisted of a large hold about 45 ft. by 20 ft. This was divided into two parts, a ward and a treatment room.

Treatment Room and Reception Ward

The treatment room measures approximately 25 ft. by 20 ft. Lying athwart the ship at the forward end of this compartment are two wooden stands 6 ft. apart and raised 4 ft. from the ground. Each stand has two grooves to receive the stretcher handles. The stretcher cot is placed on these blocks and can then be used for minor operating or first-aid work. The instrument table is a long white-painted asbestos slab running parallel with the blocks and covering over the ballast. On the far end of this is a petrol stove for heating water. This compartment also contains a slow-combustion stove, an enclosed "elsan" closet, and a fresh-water tank, laid out as shown in the diagram.

The reception ward is about 20 ft. square and accommodates twelve stretcher cots of original design and twelve G.S. stretchers. The ward also contains first-aid tables and is fitted with a cupboard and splint rack. It is ventilated by four lights in the deck and two ventilators. The deck lights are provided with wire-protected glass.

Stretcher Cot

The stretcher cot mentioned above was designed by Lieut.-Commander Hall, R.N. It consists of a rectangular piece of canvas with four flaps into which a Service stretcher can be fitted, the four corners of the canvas then being laced up. At either end is a wooden spreader stitched in the canvas, and rising from this is a triangular flap of canvas with a large metal ring hole. These can be fitted to a large wooden spreader and attached to the topping lift. The wooden spreader at either end of the cot keeps the canvas apart so that when a patient is inside it forms a canvas box with stiff sides. In addition, canvas flaps cover the patient and can be laced. It should be pointed out that holes are left in the canvas flaps through which the stretcher feet and handles protrude. The stretcher cots are carried slung athwart the ship, six on each side of the compartment. Hooks to carry one end of each cot are fixed in a stout beam, which is secured to the bulkhead; the hook for the other end of the cot is fixed to a stout wooden upright 7½ ft. from the bulkhead. There is a separate upright for each cot, and when not in use these fold flat to the deck. The beam which carries the cot hooks at the bulkhead is grooved at intervals to take the handles of six G.S. stretchers, the other ends of which are carried on the top of the inboard uprights. Thus twenty-four patients can be carried: twelve in stretcher cots and twelve on G.S. stretchers.

Method of Operating

The ship is brought alongside the craft where the patient is, and in calm weather he is taken off on a G.S. stretcher in the normal manner. He remains on this stretcher until he arrives in hospital ashore. In rough weather the stretcher cot and its stretcher are put aboard the ship where the patient is and the patient is placed in the cot. The cot is then laced up and the patient swung aboard by means of a simple topping lift and boom operated by a small geared hand-lift. The cot is lowered through the deck of the ambulance ship into the treatment room. Here the patient is attended to and receives such first aid as is practicable before he is passed through wide double doors into the reception ward.

As a number of casualties may have to be taken aboard at one time the cot hooks and stretcher racks furthest from the door are used first. All the wooden uprights on each side of the middle gangway are laid flat, and there is thus ample room

to move stretchers or stretcher cots into position. Although only 1 ft. is allowed between stretchers the treatment of patients in the ward is fairly easy. The patient on the stretcher is only 4 ft. from the ground. The patient in the stretcher

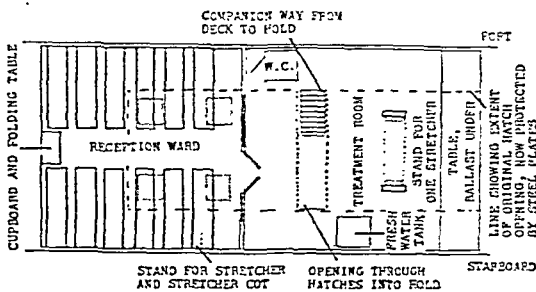

FIG. 1

FIG. 2

FIG. 3

cot is rather low, but he can be seen and dealt with without difficulty as there is plenty of space between the stretcher cot and the stretcher. Two Neil Robertson stretchers are carried in case it should be necessary to remove a casualty from a very confined space. Once this has been done he can be transferred

to a stretcher cot and slung aboard the ambulance ship. When all the patients are aboard and the ship is proceeding the hatch giving entry to the treatment room is covered in with tarpaulin.

The ship carries a crew of nine: master, mate, engineer, deck hand, corporal nursing orderly, and four nursing orderlies (airmen).

I wish to record my appreciation of the help given me in the preparation of this ship by my Commanding Officer, the representative of the Emergency Committee of the Port of London, and the Naval authorities.

REGIONALIZATION OF HOSPITALS AND HEALTH SERVICES

BY

Sir FREDERICK MENZIES, K.B.E., M.D., F.R.C.P.

At the first meeting of the Medical Planning Commission I observe that Viscount Dawson of Penn expressed the opinion that "the most important question to settle was the regionalization of hospitals and health services." Looking back over a period of more than forty years of continuous daily contact with the many and varied problems associated with the development of the hospitals and health services of London, I am profoundly convinced of the truth of the statement made by Lord Dawson. Few, if indeed any, members of our profession are so fortunately situated as the Chief Medical Officer of the L.C.C. Public Health Department for obtaining a continuous and comprehensive view of the many and varied problems concerning health and disease in a massed population of millions of people in all grades of society from the highest to the lowest, and this privileged experience was considerably extended when the L.C.C. became, by virtue of the Local Government Act of 1929, not only the largest hospital authority but also the largest public health authority in the world. In other words the organization for the prevention and treatment of disease became, for the first time, unified under one authority. Necessarily this great development brought the public health department into intimate contact with general practitioners, consultants, and specialists in all branches of medical science, voluntary hospitals and voluntary agencies of all kinds dealing with the health, happiness, social and economic welfare of the inhabitants of London. In addition it can fairly be claimed that every effort was made to extend all the facilities available for the improvement of undergraduate and postgraduate medical education. I relate these facts for no other reason than to emphasize that my opinion of the truth of Lord Dawson's statement is based upon some considerable practical experience of the trend of thought among laymen as well as medical men during the last twenty years and more.

Approach to the Problem

Another statement made by Lord Dawson at the same meeting is in my experience equally true: "War did not so much create new problems as bring to the forefront problems which had been for long in the stage of incubation." The last war (1914-18) showed the truth of this statement very clearly in connexion with the long-drawn-out struggle over the highly controversial subject of Poor Law reform. The report of the Maclean Committee, drawn up while war was still in progress, succeeded in reconciling the strongly opposed recommendations put forward in the majority and minority reports of the Royal Commission on Poor Law Reform (1909), and thereby paved the way for the introduction and passage of the Local Government Act, 1929—one of the most epoch-making Acts of Parliament during the last 100 years. In this connexion it is well worthy of notice that probably this Act of 1929 has had more to do with bringing forward the subject of "regionalization of hospitals and health services" than any other single factor, and that the duties and responsibilities placed upon county councils and county boroughs in connexion with hospital services by the same Act of Parliament may well prove to be the most important determining factor in promoting co-operation between public

health authorities and the voluntary hospitals, or alternatively the gradual elimination of the voluntary hospital system as we have known it up to the present time.

Therefore, it seems clear that all those who are genuinely anxious for the future development of our hospitals and health services upon sound principles will be well advised to approach the regionalization of these services in a statesmanlike attitude of mind in order to arrive at wise decisions. To be more precise, it means that those who are constantly preaching the virtues of the municipalization of all hospital services and those who are equally vociferous advocates of the "independence" of the voluntary hospitals must abandon for ever their silly shallow slogans and talk "horse sense" together.

Some Influencing Factors from the War

The Medical Planning Commission will also no doubt be fully alive to the fact that certain extremely important developments have taken place since the outbreak of war which must have a profound influence upon the subject of regionalization of hospitals in particular.

The first of these, to which very little attention seems to have been given in the medical press, is the practical effect or result of the enormous structural damage to hospitals of all kinds, voluntary and municipal, due to bombing. From reliable sources I have been able to collect a certain amount of useful information on this point and thereby to obtain a fairly accurate picture of the position up to the present time. I can safely say that the number of hospitals damaged, in greater or less degree, represents an actual loss of some thousands of beds, and with some practical knowledge of hospital construction and equipment one can form a reasonably approximate estimate of what it will cost to bring our hospitals back into the conditions which existed before September, 1939. It must suffice for the moment to say that the cost on a pre-war basis would amount to not less than £20,000,000, and that, if the war ended to-morrow, it would probably take four or five years at least to complete the work of reconstruction. Be it noted, however, that the war is not yet over and that much more extensive structural damage may yet take place before we can count the full cost of post-war reconstruction and re-equipment.

The next question which naturally arises is, Where is the money coming from to rebuild and re-equip? We may assume that the local authorities will be quite capable of looking after the financial requirements of their own hospitals, but, inasmuch as they will also be compelled to shoulder very heavy capital expenditure for housing, education, roads, etc., etc., it does not seem likely that they will be able to do much to help the capital expenditure involved in the reconstruction of the damaged voluntary hospitals. It looks, therefore, as if the great bulk of the capital expenditure in the case of the voluntary hospitals must come from the State. I submit that voluntary contributions will not suffice to meet the situation, because the amount of capital expenditure involved will be too great. If, therefore, it must mean grants of some millions of pounds from the State or the local authorities, or both, upon what terms and conditions are Parliament and the local authorities going to allow public funds to be ladled out for the benefit of voluntary hospitals? It seems to me to be obvious that in such circumstances much will depend upon what view is taken by the Government of the day upon the whole subject of "regionalization of hospitals and health services." We do know the views of the present Minister of Health and his predecessor, Mr. Malcolm MacDonald.

Another interesting aspect of this question of the reconstruction of hospitals, whether municipal or voluntary, is the fact that in connexion with the Emergency Hospital Service many thousands of hospital beds have been provided either by means of completely new hospitals on new sites outside our great towns or additions to existing hospitals wherever selected for this purpose. Many millions of pounds have been spent out of public funds for this purpose during the last two years. It is obvious that such hospitals cannot simply be scrapped after the war is over. They must so far as possible be dovetailed into existing hospital services or in some way linked up with a regionalization scheme.

Post-war Distribution of Population and Industry

This brings me to another much-discussed problem—namely, the geographical distribution of industry and population. We must assume that one of the outstanding consequences of the war will be that Lord Reith's department will put forward a new conception of town planning with all its implications in relation to housing, transport, education, health, and hospital services, etc. The subject is much too complicated and comprehensive to be more than merely hinted at here as something which "must be borne in mind," but, at least, we can say that it is a factor to be reckoned with in considering the regionalization of hospital and health services.

Finally, I would like to draw attention to the fact that "regionalization" is one of those questions which has been "for long in the stage of incubation." Anyone who has been intimately associated with national and local government problems during the last twenty years could not help seeing its gradual development. War conditions have succeeded in forcing it to the forefront much more rapidly than would otherwise have been possible in peacetime. We have seen evidence quite recently of its application to the fire services of the country, and we are all familiar with the "Civil Defence Regions" which have been in operation since the outbreak of war. We shall see it ere long in the formation of new local government areas. Again Parliament may decide after the war that these war-time regions shall become permanent, and that the time is ripe for the decentralization to such regional authorities of many of the powers and duties now exercised by Parliament centrally from Whitehall.

For these and many other reasons "regionalization" is the order of the day. It is definitely on the move. It may become our conception of the "New Order" or the "New Deal." It is, anyhow at the moment, the vogue or the fashion or whatever you like to call it. Let us hope and pray that "regional areas" for any and every purpose will be contemporaneous and not overlapping, and, finally, let us give up "kicking against the pricks" and awaken to the fact that the regionalization of hospitals and health services is in reality only part of a great new movement which is bound to come to maturity in the very near future, and, therefore, let us hope the Medical Planning Commission will make a good job of this part of their great task while there is still time for some real hard concentrated thinking.

MEDICAL ADMINISTRATION IN FOUR EUROPEAN COUNTRIES

An interesting meeting was arranged by the London Association of the Medical Women's Federation on June 26 when the subject of medical administration and services in their respective countries was expounded by an Austrian, a Czechoslovak, a German, and a Norwegian. The conditions they described were, of course, those obtaining before 1933 in Germany, before 1938 in Austria, before 1939 in Czechoslovakia, and before 1940 in Norway. Dr. JANET AITKEN presided.

Austria before 1938

Dr. GLATTER, late of Vienna, described the struggle over social insurance in Austria, in particular the economic conditions of the medical profession after the last war, when there was a large surplus of doctors (10,000 in Vienna alone for a population of under two millions); compulsory health insurance covering 60% of the population; no means test, so that any person, however relatively well off, could come under the panel system; and a decrease in private practice to such an extent that only doctors of international standing could earn a living by that means. The professional medical organizations had to fight for recognition, resulting in strikes and lock-outs at certain institutions. Some advantages were presently gained, but not until the law of 1937 did the doctors secure most of their demands, their professional interests being effectively safeguarded. Ironically, however, the law never came into full operation, Austrian social insurance being superseded by the German law.

Pre-Nazi Czechoslovakia

Prof. JULIUS LOWY, formerly of Prague, described medical training in pre-Nazi Czechoslovakia. The student was

admitted to the medical faculty of one of the four universities at the age of 18 or 19. The preparation for a medical career cost only about £500, as compared with an average of £1,500 in Great Britain. Everyone, regardless of his means, was given the opportunity to study, but provisions were made to weed out unsuitable candidates. If a student failed in one examination he could sit a second time without formality. If he failed a second time he could only sit by special permission, and if he failed a third time he could only sit again by starting the whole system of his studies *de novo*. It was exceptional for the newly qualified student to set up in practice sooner than two years after qualification; he held hospital appointments for two or three years. The insurance companies did not appoint panel practitioners unless they had held hospital appointments for at least two years and had completed a course in social medicine. Before a man was permitted to specialize he had to spend four or five years in hospital. Prof. Lowy described the system of health insurance, which included specialist as well as general practitioner services, maternity benefit, and hospital charges. Insured patients had free choice of doctor, and they were also able to see consultants and specialists at specified times.

Health Insurance in Germany

Dr. F. W. JACOBSON, formerly physician at Virchow Hospital, Berlin, said that in Germany the amount of private practice was very small; 80 or 90% of the population was insured. The income limit for compulsory insurance was 3,600 marks (£180), but there was a large class of voluntary insured persons and also the dependants of the insured who were attended on a panel system. There was free choice of doctor, and patients might be treated by their panel doctor at home or at his surgery or at the hospital. To prevent unreasonable use of the services of panel doctors every prescription cost the insured person 25 pfennig (3d.), though in a case of bona-fide illness the amount was not insisted upon for repeat prescriptions. Differences between the doctors and insurance companies were settled by a body consisting of ten representatives of each side with three deputies from the Ministry of Labour. A panel doctor could not be appointed until two years after he had qualified, and of that two years he must have spent at least three months as assistant to a panel doctor and for six months have been in an institution where he could receive instruction in social and State medicine. The qualification for panel specialists required four years of special instruction in surgery, internal medicine, children's diseases, and urology, or two years in orthopaedics, ophthalmology, dermatology, and venereal diseases, and nervous diseases and psychiatry. Doctors in charge of clinics or out-patient departments were not allowed to hold more than one appointment. The heads of hospital departments received much less pay than their chief assistants, but the latter, unlike the former, were not allowed private practice. Specialists in Germany were not congregated in particular quarters; there was no equivalent to Harley Street in Berlin. Every suburb had its recognized specialists. He added that in recent years there had been a good deal of Nazi dilution. For example, the additional two years after qualification was now interrupted by a compulsory period at a labour camp.

Centralization in Norway

Dr. DEDICHEN, inspector-general of Norwegian Health Service in Great Britain, said that in view of the geographical, social, and economic peculiarities of Norway it was necessary for the State and municipal authorities to take over and centralize very much of the health and hospital work of the country. The 380 public health officers represented about 18% of the Norwegian medical profession. There were still some private hospitals in Norway, some of them run by religious bodies, but they were becoming of less importance. The best of the municipal hospitals were in every respect up to the standard of other countries. The increasing demand for public health services had meant a certain limitation of the principle of free choice of doctor. Public health insurance was on a wide basis, and the numbers of non-insured were small. Reforms needed were a better organization of post-graduate education and a closer collaboration between general practitioners and the hospitals.

In reply to questions Dr. JACOBSON said that in Germany dependants were insured at a lower rate of contribution but received less benefits. The doctors did not receive their panel fees directly from the State nor from the insurance companies, but through their own medical organization. There was a ratio between the contribution of the insured person, the fee paid to the insurance organization, and the amount of attendance and service for the patient. Dr. DEDICHEN said that in Norway the income for sickness insurance was derived as to six-tenths from the insured persons, two-tenths from the

State, one-tenth from the municipality, and one-tenth from the employers. Asked how the ordinary patient arrived on the doorstep of the right specialist, Dr. JACOBSON said that from youth the German received more instruction about hygiene than in this country; much more teaching was given to girls concerning motherhood and ante-natal care. Parents knew where to send their children suffering from various ailments. In reply to another question, Dr. GLATTER said that there was no difference in Austria between medical men and medical women in rate of payment and opportunities for promotion; and Dr. JACOBSON said that it was the same in Germany, where many of the chief assistants in surgical and other departments were women.

AIR-RAID PROTECTION

FURTHER REPORT BY THE HALDANE COMMITTEE

The *Evening Standard* of May 7 reported that the Prime Minister asked Mr. Lloyd George whether he advocated the widespread provision of bomb-proof shelters, or of shelters proof only against blast; to which Mr. Lloyd George replied: "If you do it on a sufficiently large scale you can do it against both." But Mr. Herbert Morrison said in the House of Commons: "We are ready to consider deep-shelter proposals on their merits, but there must be taken into account questions of labour supply, materials, and so on." Whether or not there is shortage of these at present, according to the latest report of the National A.R.P. Co-ordinating Committee time and material have up to the present been wasted in the construction of surface shelters. It has been learnt that not one of a thousand people using a "Haldane" type shelter was injured when a bomb exploded near-by. In some places the public have been forbidden the use of deep shelters already existing, various contradictory reasons being given for these measures. For instance, one shelter used regularly by 2,500 people was at first stated to be unsafe, and yet was later said to be required for essential work.

Protection against Gas

Meanwhile, the question of protection against poison gas is being discussed apart from the problem of shelter against bombs. The Co-ordinating Committee points out that in the official leaflet, "What to do about Gas," people are recommended to "go upstairs," regardless of the fact that bombs may be falling, and that in any case if liquid gas is sprayed the top floor of a house may well become dangerous. There is no mention of whether the shelters should be used in these conditions, or whether people in an Anderson shelter should go to their houses if the rattles sound. In the committee's opinion these anomalies can be overcome only by the construction of large bomb-proof shelters provided with filtered air from outside. The committee further recommends that people should be told that very little gas gets into a room if the doors are closed and there is no draught up the chimney, and that everyone, not only the mothers, should be taught how to adjust babies' protective helmets and how to use the accompanying pump. Among other points brought to the attention of Mr. Morrison are the omission from the leaflet of any mention of the possible need for temporary evacuation of areas suffering from persistent gas attacks, the necessity for rest for those who have been affected by phosgene, and the early treatment of gas casualties. It is considered that fears of blistering should be allayed by giving publicity to the fact that, though a hundred thousand British soldiers were injured in this way during the last war, not one died as a result. The committee also asks that the amount of safety afforded by the ordinary civilian gas-masks against arsine should be made clear. In August, 1938, a demonstration showed that arsenical smokes could penetrate the mask filter. Since then, however, the supplementary "context" filter has been issued, but no statement has been made about its adequacy in dealing with arsine.

Distress in Bombed Towns

In the midst of this concern for the future, the Co-ordinating Committee is not forgetting the present distress among the homeless in badly bombed areas. Arrangements for feeding the homeless are improving, but are still inadequate. In the Coventry raids of April for instance, the Queen's Messenger convoy sent from London arrived too late to be of any help. People were being advised to boil all water, but there was no water to boil, and many were without gas or electricity; no steps were being taken for emergency supply by such means as, for example, the erection of a few boilers in the streets.

NATIONAL FLOUR: CRITICISMS FROM CHESHIRE

The Cheshire Local Medical and Panel Committee, which has several enterprises to its credit—the "Medical Testament" will be remembered—has been having a brush with Lord Woolton on the question of national flour for bread.

Full-germ Wholemeal Bread

In March, under the stimulus of its honorary secretary, Dr. L. J. Picton, the committee forwarded to the Minister of Food a memorandum urging that genuine wholemeal bread should be made generally available and that the 85% extraction flour which the Ministry had announced, if it contained the full germ, should be the only "white flour" of the future. It was pointed out to the Minister that the removal of the embryo in steel-roller milling is the reason why white bread is never felt to be as satisfying as wholemeal, and why ten loaves of white only go as far as nine of wholemeal. The germ is the only part of the grain which contains oil, the richest known source of vitamin E. The reason for the removal of germ has been to maintain the keeping properties of flour, but in the view of the Cheshire committee if wheat is stored in widely scattered parcels inland instead of at the big silos at vulnerable ports the country miller will get a chance to make wholemeal, which, if it were wanted, could be sieved or "bolted" through wool or silk as was done seventy years ago before the introduction of the roller mills, and such flour could be used at once. Some millers extract the wheat germ, treat it with superheated steam and restore it, but vitamin B₁, of which there is a large proportion in the germ, is destroyed by great heat.

The reply of Lord Woolton, dated April 19, was that millers had been instructed when milling national wheatmeal (of 85% extraction) to take all possible steps to include the maximum amount of germ, and that he was advised that they would not find it necessary to remove the germ for heat treatment and mix it back.

This assurance was gratefully received, but in May there was published a memorandum by the Medical Research Council (*British Medical Journal*, May 31, p. 828) which on two grounds aroused misgiving in vigilant Cheshire. It described two alternative milling processes, one requiring a rearrangement of milling machinery to produce the 85% flour, the other depending upon the addition to the white (73%) flour of "combinations and other fractions." The second was admittedly an inferior method, resulting in a synthetic and unreliable product, but allowable pending an alteration of machinery. In a further letter to the Ministry of Food, dated June 12, the Cheshire committee urged that (1) the genuine 100% meal of the wheat, with neither extraction nor addition, should be made increasingly available; (2) the method of milling the 85% flour by a rearrangement of milling machinery should as soon as possible replace the alternative synthetic method; (3) ordinary white flour should be withdrawn and the 85% flour allowed to do duty as white, "as the sieved wholemeal did up to the unfortunate German innovation in 1872." This innovation, really Hungarian, was the introduction of milling by grooved rollers.

Fortification with Calcium

The other matter which aroused some question was the statement in the Medical Research Council's memorandum that calcium carbonate (as *creta praeeparata B.P.*) is to be added to flour, 7 oz. to 280 lb. of ordinary white flour and double that amount to the new 85% flour. The main reason given is that more calcium must be added to diet to maintain a sufficient supply for health. An increased amount has to be added in the case of the 85% flour because that flour contains more of its phosphorus as phytic acid, which the lime is required to neutralize. The Cheshire committee protests to Lord Woolton that once flour is fragmented and deprived of this or that fraction the balance of its nutrients is disturbed, and such an addition as chalk brings in new problems. It also points out the richness of wholemeal in minerals which are deposited just inside the groove or crease in the wheat berry. With stone milling these minerals were ground up with the rest of the flour and contributed to the acceptable taste of the wholemeal, but modern milling is designed to "break the staff," even entirely to eliminate these minerals, which the millers call "crease dirt," resulting in a whiter but insipid flour. A quotation from *Leviticus* is commended to Lord Woolton: "When I break the staff of your bread . . . ye shall eat and not be satisfied."

Lord Woolton has agreed to publication of this interesting correspondence.

MINERS' PHTHISIS MEDICAL BUREAU

The report upon the work of the Miners' Phthisis Medical Bureau, Union of South Africa, for the three years ended July 31, 1938, states that the general incidence rate of silicosis among the working miners in 1937 to 1938 was the lowest ever recorded. This incidence rate—7 per 1,000—represents a fall of 64% from the figures obtained eleven years previously. During the period under review there was a considerable increase in the work of the bureau, due to the greater number of European miners and native labourers employed through the expansion of the mining industry. The report stresses the need for further control of the dust produced by machine drilling, which is, apparently, the most important remaining individual problem in the reduction of the incidence of silicosis. Three characteristic features in the type of silicosis encountered to-day among the gold miners of the Witwatersrand are referred to. First, it is a condition usually contracted as the cumulative result of many years' previous exposure to the inhalation of siliceous dust. Secondly, it is a progressive disease, and it is the added predisposition to active tuberculosis in lungs containing siliceous dust which is the predominant factor in the ultimate advance of a majority of cases to grave incapacitation or even death. Thirdly, it is also a chronic disease. Cases which are markedly infective from the outset progress rapidly, and the patients may die within the year, but the average expectation of life of those who have contracted the disease in a detectable form is fifteen to sixteen years. Indeed, in many cases the disease may reach and maintain a condition of prolonged or apparently indefinite arrest.

Reports of Societies

SULPHONAMIDES AND BACTERIA IN URINE

At a meeting of the Section of Pathology of the Royal Academy of Medicine in Ireland, with Dr. R. A. Q. O'MEARA in the chair, Dr. P. A. McNALLY read a communication from Prof. J. W. BIGGER and himself on the action of certain sulphonamide drugs on the growth of bacteria in urine.

They had tested sulphyridine (M & B 693), sulphanilamide (sulphonamide P, B. W. & Co.), sulphathiazole (M & B 760), and sulphamethylthiazole (M & B 838) on *Proteus vulgaris*, *Bacterium coli*, *Staphylococcus pyogenes*, and *Streptococcus faecalis*, all isolated from the urine of patients suffering from cystitis. *In vivo* the destructive effect was facilitated by the presence of polymorphonuclear leucocytes and *in vitro* by the smooth inorganic walls of the containing vessel. Many workers had found that the *in vivo* efficiency closely followed the *in vitro* action. Strict controls were necessary, especially with *Proteus vulgaris*, which, in the absence of the drug, produced a bactericidal pH in the urine in twenty-four hours *in vitro*. The most effective of the four drugs for this organism and for *Bact. coli* was sulphyridine, and the least effective was sulphanilamide. Sulphathiazole was disappointing against *S. pyogenes*, sulphyridine being more effective at equal concentrations. Using an artificial bladder, by which it was possible to create to some extent the conditions prevailing in the human urinary tract, the authors found that sulphyridine and sulphathiazole were more effective than in flasks; the organisms seemed to develop some drug-fastness when acted on by low initial concentrations of the drugs. In the treatment of urinary infections clinicians should determine the causative organism, use sulphyridine for *P. vulgaris* or *Bact. coli*, arrange the dosage so as to secure the highest permissible concentration in the urine from the start, and make sure that the urine was alkaline.

The CHAIRMAN pointed out the difference between blood and urine in that phagocytic action was almost absent in the latter. The mode of elimination of the drug might vary in different individuals. Mr. T. J. D. LANE said he had found in two cases that no amount of sulphanilamide would sterilize the bladder. Dr. BRENDAN O'BRIEN suggested that it might be interesting to use urine from patients who were being treated with large doses of the drug for pneumonia or meningitis, and see how it compared with simple solutions of sulphanilamide. Dr.

EDWARD SOLOMONS asked if infections of the bladder and kidney could be treated from below. Dr. A. R. PARSONS thought that it might be wise to give drugs to increase the alkalinity of the urine.

Dr. McNALLY, in reply, said that the highest concentration of free sulphonamide in the urine that he had found was 400 mg. per 100 c.cm. The maximum that could be dissolved *in vitro* was 100 mg. per 100 c.cm., so it would be no use to introduce the drug from below. If the pH in the bladder could rise to bactericidal limits it would probably damage the bladder wall. *In vivo* the highest pH reached in *P. vulgaris* infections had been 8.4.

GROWTH OF COLIFORM BACILLI IN WATER

At another meeting of the Section of Pathology of the Royal Academy of Medicine in Ireland, when the President, Dr. D. M. MITCHELL, was in the chair, Mr. HAVELOCK NELSON read a paper by Prof. J. W. BIGGER and himself on the growth of coliform bacilli in water.

Prof. Bigger had previously declared that these bacilli would sometimes multiply in tap water, especially when it was boiled, autoclaved, or filtered through a Pasteur-Chamberland filter. The statement had been contested by Col. Harold, who had suggested that the growth was due to the filter or rubber connexions of the filter and not to the water itself. The present investigation showed that the water still supported growth when no rubber was present in filtration. The inner dressing of the rubber (talc, French chalk) had proved an excellent medium in distilled water. Growth still occurred when the talc had been roasted in a muffle furnace for several hours. The water, which was carefully tested in controls, did not support growth, nor did the cotton plug, for the organism grew in talc and distilled water if the neck of the flask was covered with an inverted heater. The broth in the inoculum was not the answer, and the sole remaining source of nutrient substances was the atmosphere. A dozen or so other insoluble inorganic substances also supported growth.

The PRESIDENT asked if the organisms, owing to some property in these growth-producing substances, were able to get carbon dioxide and nitrogen from the atmosphere as their source of energy and nutrition. Dr. R. A. Q. O'MEARA said the work was extremely important from the public health point of view. It was possible to train an organism to revert to a primitive metabolism, and these organisms were relying on something even simpler than carbohydrates for their growth, possibly having reverted to a bygone age.

At the annual general meeting of the Society for Relief of Widows and Orphans of Medical Men, with Sir William Willcox in the chair, the report for 1940 was presented and approved. During the year sixty-one widows and three orphans had received £4,642 10s. Owing to enemy action, four of the widows had been compelled to vacate their homes. The total membership of the society is £29, of whom 169 are life members. Membership is open to any registered medical practitioner who at the time of his election is resident within a twenty-mile radius of Charing Cross. Relief is granted only to the widows and orphans of deceased members; widows with a yearly income of over £125 are not eligible for relief. Grants to orphans cease on their attaining the age of 16. Widows under 65 years of age at present receive £65 a year, those over 65 £70, and orphans receive £70. There is a special fund from which grants are made to orphans over the age of 15, to enable them to study for some professional or business career. The grant from this fund is usually fifty guineas a year for five years. Full particulars of the society may be obtained from the secretary, 11, Chandos Street, Cavendish Square, W.1.

Civil Defence workers transferred from the area of their homes and persons attending industrial training establishments away from home are to be admitted to E.M.S. hospitals when they require in-patient treatment, and the cost, after deduction of the patient's contribution, will be met by the Ministry of Health. Transferred war workers admitted to hospital are to receive an allowance of 5s. a week towards such expenses as would not be incurred in their home town.

Correspondence

Wholemeal Bread

SIR,—In the *British Medical Journal* of May 31 (p. S28) the Medical Research Council gave their second memorandum on bread, and set out their specification for national flour of 85% extraction. Apparently they have two criticisms of wholemeal bread: first on account of its roughage and second on account of its keeping properties. The M.R.C. state that it is undesirable to increase the roughage in wartime diets, but they give no grounds for this statement. The only reference I can find in the literature is work by Bickel and Fleischer (quoted by Copping, *Nutr. Abstr. Rev.*, 1939, 8, 555), who find that wholemeal bread in amounts under 3½ oz. hastens the passage of a barium meal, but in amounts over this tends to delay it. The statement of the M.R.C. requires support, for the bran they propose to exclude contains 7.8 mg. Fe per 100 grammes compared with 1.0 in white flour, which, in these days of anaemia, is of great importance, as the iron is very well absorbed. It must be remembered, too, that until recent years wholemeal was the only meal available and was eaten in double the quantity.

In answer to the M.R.C.'s second criticism of wholemeal, I have seen the interim results of a series of experiments on the keeping properties of wholemeal. Samples from three different sources have been stored in a bakery for six months at a temperature not exceeding 60° F., and at the end of this time were in sound condition. So the statement of the M.R.C. that flour of 85% extraction could be kept under reasonable conditions of storage for four to six weeks or longer, though true, is misleading.

The M.R.C. recommend 85% extraction flour and suggest two methods of producing it. Flour (i) is nearer to white flour, but needs changes in milling machinery. Flour (ii) requires no change in machinery, but, according to their specification, is open to variation. The flour is made by adding to white flour the germ and fine bran which have been separated. As some mills do not separate the germ the wheatings from these will contain more bran and less germ. Flour produced from these mills will be darker and contain more roughage than that produced by other mills. It is doubtful, therefore, if the specification given for Flour (ii) justifies the analysis. Nevertheless the M.R.C. recommend the production of this flour, as it can be made without delay. In other words, an 85% extraction flour, which will vary from off-white to the pale brown of wholemeal, is advocated in spite of the fact that it is less nutritive and no easier to manufacture than wholemeal.

The M.R.C. recommend the addition of calcium salts to all wheat flours. When this is done the nutritive values of 11 oz. (the average daily consumption) of each of the three breads are found to be as follows:

	Starch grammes	Prot. grammes	Ca mg.	Fe mg.	Vit. B I.U.	Vit. E mg.
Wholemeal bread + Ca	136	26	340	6.7	310	0.8
85% extraction bread + Ca	142	25	353	4.0	260	0.6
White bread + Ca	168	23	267	2.7	70	0.0
Average daily requirements	420	50	670	13.0	550	2.0

I repeat, therefore, that without further evidence on the action of bran in the alimentary canal the M.R.C.'s case for 85% extraction bread is not a good one. It is significant that in Eire at this moment flour of 95% extraction is the only type allowed to be manufactured for bread-making purposes. In South Africa the Secretary for Agriculture has proposed a standard loaf of 90% extraction.

This, however, is not the whole problem before the Government, for there are large stocks of white flour in the country. The addition of vitamin B is a small step to improve the nutrition of white flour, but the urgent necessity is the addition of Fe. The M.R.C. state that the addition of Fe salts might interfere with the nutritive value of other components of the flour. Perhaps they might obtain some

information from Canada or the U.S.A. The Canadian Council on Nutrition and the National Research Council of the U.S.A. seem quite happy about it.

To make this white flour as nutritionally valuable as is reasonable it is necessary then to add imported germ, Ca, and Fe salts. While this is being done the baking machines, which make a large proportion of our bread, can be adjusted for the preparation of wholemeal bread.—I am, etc.,

Leeds, June 30.

R. A. MURRAY SCOTT.

Oxygen Administration

SIR,—In your issue of June 28 (p. 980) there is an advisory article entitled "Hospitals and Gas Casualties. Notes on Reception and Management." With regard to treatment of gas cases with oxygen it is stated that "he [the medical officer in charge] should ensure that all those likely to be concerned understand the use of the nasal catheter, the B.L.B. mask, the spectacle-frame outfit. . . ." Other equally efficient methods of oxygen administration are not mentioned. Advisory articles have recently repeatedly excluded all other methods, although in one of the earliest pamphlets—namely, Memorandum No. 5 (England and Wales) Emergency Medical Services—it is admitted (p. 2) that there are other equally effective methods.

In a case of widespread gas attack it seems reasonable to advocate any efficient method since there is certain to be a shortage of apparatus. Among these other methods which have been passed as efficient by clinicians is the box-mask or face-tent method (*British Medical Journal*, 1938, 1, 1260; *Lancet*, 1937, 1, 82) and its modifications. A box mask requires no valves and may be made from a cardboard box, sticking plaster, lint, and a rubber tube in ten minutes. The modification of Dr. Alice Rose and Mr. Holmes Sellors (*Lancet*, 1940, 1, 648) is also readily constructed from materials provided in a hospital. This face-mask method has also been used with success by Mr. T. W. Adams (*Lancet*, 1940, 2, 474) and the late Dr. E. P. Poulton, and also by well-known specialists in America and in France. In hot climates and out-of-the-way places where rubber and other materials deteriorate rapidly a readily constructed cardboard mask has its advantages. This has been pointed out in Australia.

The recommended methods certainly have their disadvantages and setbacks. They are not particularly becoming. Recently Professor R. V. Christie and Dr. Hadfield (*British Medical Journal*, 1941, 1, 77) tried to apply the B.L.B. mask and the nasal tubes to a patient, but he refused to wear them. Again, the B.L.B. mask is certainly not wholly fool-proof, unless the mouth is also covered. This has been admitted by those who recommend the B.L.B. mask (*Proc. roy. Soc. Med.*, 1940, 33, 481). If the mouth is covered as well as the nose, then there is no great difference from the face tent in respect to the area of the face covered. There is also "a valve" (in the latest type, of sorbo rubber) to operate in the B.L.B. mask, and this must impede respiration in the very weak patients.

With the nasal-tube method cocaine is often necessary, but this does not altogether abolish the discomfort due to the irritation of a constant rapid flow of oxygen over the mucous membrane. Again, there is no doubt that the addition of a face tent increases the efficiency of nasal tubes and reduces waste of oxygen.

As the late Dr. Poulton found, there are cases, particularly in children, which can be treated adequately only in some modification of Sir Leonard Hill's bed tent. It might be advisable to keep all available tents at hand.—I am, etc.,

London, N.W.3, June 30.

J. ARGYLL CAMPBELL.

Medical Aid for China

SIR,—The China Medical Aid Committee appeal for your interest and assistance to carry on its work.

For four years China has held out against the aggressor and war has produced devastation and destruction, not only of homes and industries but of hospitals, with an increasing number of wounded, sick, and crippled needing medical aid. China, with slender medical resources, has valiantly attempted to deal with this suffering, and Dr. Robert Lim, Director of the Chinese Red Cross, has set up numerous medical units for treating the sick and wounded and for training first-aid workers for the fighting Services; but in China the number of doctors with modern training is few, and in 1939 Dr. Lim appealed to the Western world for help.

In 1939 this committee, in co-operation with a Norwegian committee, sent out some twenty doctors who have now become heads of Red Cross units and are striving with inadequate materials and very little trained assistance to create a medical service in the front line. The Chinese Red Cross, short of funds, asks us to maintain, at least in part, the doctors we sent out two years ago. The following is taken from a recent report to us:

"Moreover epidemics of typhus, typhoid, and relapsing fever have taken terrifying toll. In the absence of qualified people to guide the inhabitants in elementary self-protection, whole families have been wiped out and entire villages and districts have been devastated by such epidemics. Infantile mortality is very high. Over 70% of the population of the North-West suffer from trachoma and this means thousands of blind. Millions of people have not a single doctor to give advice and help to sick and wounded, and there are no medicines to treat disease, prevent epidemics, and protect the newborn."

The army services alone require 30,000 doctors and there are but 5,000 in the whole country. Our contribution to this immense deficiency has been small but it has been appreciated. Dr. Lim, writing to us in March of this year, says, "Let me say how grateful we are here to all of you for still taking an interest in poor China while England is being so battered from the air. It is simply splendid of the British people, and the common aim of our armies to struggle on against aggression and the example given by Britain has given the people of China a new stimulus to fight on."

Please let us have your utmost assistance and let China see that we appreciate to the full, amidst our own troubles, the great service to our cause afforded by her continued resistance to aggression. Your readers' support will be greatly appreciated. Please forward donations to Dr. E. R. C. Hambly, Treharrock, Long Grove, Seer Green, Bucks.—I am, etc.,

London, July 1.

HORDER.

Secret Remedies: Loophole in New Bill

SIR,—In connexion with the Pharmacy and Medicines Bill now being introduced in the House of Commons, it would appear that if, instead of making the declaration of all ingredients of a hitherto secret remedy compulsory, the proprietors are allowed to state only so-called active ingredients, an easy loophole will exist for fraud and evasion by dishonest purveyors of certain advertised articles. For example, a secret so-called cure for alcoholism, which the analysis in your publication *More Secret Remedies* showed to contain over 75% alcohol by volume with only minute traces of brucine and strychnine, would on a partial declaration be well calculated to dupe the lay public into imagining they were expending their money on potent medicaments magically blended, whereas they would in reality be purchasing something which, unless controlled by a qualified person, would be actually deleterious to them. It is to be hoped that those piloting the Bill through the House will note and stop this loophole.—I am, etc.,

A. E. CARVER, M.D., D.P.M.

Nuneaton, June 6. Medical Director, Caldecote Hall.

Tuberculosis in Recruits

SIR,—In a note on detection of tuberculosis among recruits (*Lancet*, 1940, 2, 518) I expressed the hope that others would publish their findings so that an inquiry could be made into the criteria for reference to tuberculosis officers. This hope has been admirably fulfilled in the paper of Dr. Sidney H. Graham and Mr. Mostyn Davies (June 21, p. 920). Graham and Davies have, however, in my opinion, failed to stress the basic aim of such an investigation. This is not so much how many tuberculous recruits are discovered by reference to tuberculosis officers as how many are *not* detected and are accepted into the Services. Of 1,869 recruits first seen by tuberculosis officers in Wales, 108 (5.7%) had active pulmonary tuberculosis. But how many recruits attended the Medical Boards? And, on the basis of published studies of the incidence of unsuspected tuberculosis, how many among them were in fact suffering from active tuberculosis? I have been told that between 1 and 2% of recruits are usually referred to tuberculosis officers. Even at the higher figure, the 3,049 referred recruits in Wales (including those already known to the dispensaries) would

represent a group selected out of about 150,000 men. The incidence of unsuspected active pulmonary tuberculosis in over 100,000 unselected Australian recruits was 0.56% (Galbraith, *British Medical Journal*, 1941, 1, 609). For well-known reasons this incidence is probably much higher in Wales. But even if we assume it to be 0.56%, the expected cases of active pulmonary tuberculosis among the Welsh recruits would be 840. As only 105 cases were discovered, at the very lowest estimate 732 recruits with active pulmonary tuberculosis were admitted into the Services. Thus the criteria at present used for referring recruits to tuberculosis officers led to the detection of less, and probably very much less, than 13% of the men who might reasonably be expected to have had unsuspected active pulmonary tuberculosis when they attended the Medical Boards.

Graham and Davies do not comment on another interesting finding. Of the 108 active pulmonary cases, 79 (73%) are stated to have been sputum-negative; and I note that among the 573 males aged 18 to 35, other than recruits, referred to the same tuberculosis officers in 1940, 282 (49%) were sputum-negative. If this difference is significant it deserves explanation. And are so many "early cases" really being discovered in Wales? Or are the sputum examinations at the dispensaries necessarily superficial, and is therefore the distinction between "T.B.+" and "T.B.−" merely misleading and should it be dropped?

One more point. Commenting on the significance of a previous "pleurisy" as mentioned by the recruit, Graham and Davies write that among the 3,049 referred recruits, 499 stated that they had had pleurisy; 116 (23%) subsequently developed pulmonary tuberculosis. The figure 3,049 includes the 1,180 recruits already known to the dispensaries. Of more direct interest would be the percentage of tuberculous recruits among those who had given a history of pleurisy to the Medical Board and had not previously been seen by a tuberculosis officer. For it seems possible that the group previously seen would have discussed the "pleurisy" with the tuberculosis officer; at the Medical Board later such a history might be given only if it had been "approved" by the tuberculosis officer.

I sincerely hope that the paper by Graham and Davies is only a preliminary communication, and that further study of their valuable material is being carried out by them.—I am, etc.,

Staines, June 23.

G. GREGORY KAYNE.

Carriers of Tuberculosis

SIR,—I have just seen Dr. E. Fraenkel's letter in your issue of June 21 (p. 946). My paper in your issue of May 3 was necessarily somewhat compressed for obvious reasons, and I should have liked more space in which to elaborate the thesis of "tuberculosis carriers." Dr. Fraenkel appears to hold the view that all individuals with tubercle bacilli in the sputum have an *advancing* process. In many cases this is clearly untrue, for patients with a positive sputum may be kept under observation for a number of years and may show little or no change in the x-ray picture of the chest. Surely these people do not suffer from tuberculosis in the same way as a patient who has symptoms of toxæmia or signs of destruction in the respiratory tract, such as cough, sputum, and hæmoptysis. I would not regard such patients, in fact, as having active pulmonary tuberculosis, although I would not form an opinion to this effect until the patient had been under observation for many months, but I do not want to split hairs with Dr. Fraenkel or anyone else on this point.

I quite agree that any patient with a positive sputum is a potential danger to himself, and there is not one word in my paper to suggest the contrary. My main purpose, however, was to suggest that patients who might have no symptoms or signs of active tuberculosis may very easily be a menace to others, and I wished to stimulate practitioners in general to have sputum examined for tubercle bacilli much more frequently than is the case at present. Surely it is important that this should be done, as overcrowding and rationing together may quite well increase susceptibility to tuberculous infection. Dr. Fraenkel would, I am sure, admit the existence of typhoid carriers, and such individuals may develop bone abscess or cholecystitis thirty years after their original infection. Presumably in the interval they were not suffering from typhoid fever.—I am, etc.,

London, W.1, July 3.

JAMES MAXWELL.

Bacteriology of the Closed-plaster Method

SIR,—I have had opportunity to sample the bacteriological flora of varicose ulcers at a large hospital clinic where treatment has been by enclosure of the whole leg in elastoplast, which is left on, in most cases, for two or three weeks at a time. As in the closed-plaster method discussed by Dr. Jean Orr-Ewing, Mr. J. C. Scott, and Mr. H. D. Gardner (June 14, p. 877), the virtue of this method appears not to be related to the bacteriology as a rule, but would seem to depend on biochemical and physical factors.

Strict aseptic procedures not being possible in such a clinic, cross-infections were seen to occur. Among others, fifteen suitable cases were followed through. *Ps. pyocyanea* appeared suddenly, affecting six cases, then almost died out after about two months. Of five large ulcers which healed particularly well—that is, in two to five months—three showed *Ps. pyocyanea* as follows: (1) *Staph. aureus* was replaced by *Ps. pyocyanea*; (2) *Staph. albus* followed by *Ps. pyocyanea*, and later by *Ps. pyocyanea* with enterococcus; (3) *Ps. pyocyanea* alone; (4) *Staph. aureus* and *citreus*; (5) *B. coli*. But other cases showed average or slow progress in the presence of a variety of organisms including *Staph. aureus*, enterococcus, *B. coli*, *proteus*, diphtheroids, and *Ps. pyocyanea*. *Str. pyogenes* was found in two patients who had resistant and "angry" legs. Direct smears were made and the amount of phagocytosis noted. This bore no obvious relation to progress.

I thank Dr. Stuart McAusland for the opportunity to follow these cases.—I am, etc.,

Liverpool, June 27.

JOY CROBIN LOWE.

Discission of Secondary Cataract

SIR,—I read with interest Dr. F. E. Preston's letter (May 24, p. 797) suggesting the use of mydrin before discission after cataract extraction. I have tried this method on a few cases and found it very helpful, especially when the capsule was of a rather dense nature. Mr. Bishop Harman's method of using two Ziegler knives I have found most helpful on many occasions, the disadvantage probably being two penetrating wounds instead of one.

With the present various methods of intracapsular extraction discission is not so common as some years ago. For those who still use the orthodox method of expressing the lens it may be helpful to suggest a procedure which I have found very useful in my own work. This is very simple, and reduces the necessity for needling to a minimum. It is as follows. After using the cystotome to tear the anterior capsule, while this instrument is still in contact with the lens, a side-to-side or rocking movement of the lens is performed. This breaks away the ligament fibres and usually causes the lens to come forward in its capsule. It can then easily be expressed in the usual way, and, to my mind, with less likelihood of loss of vitreous than in the usual intracapsular methods.—I am, etc.,

Norwich, June 23.

W. E. RUTLEDGE.

Chemoprophylaxis of Rheumatic Fever

SIR,—I was much interested in your annotation on "Chemoprophylaxis of Rheumatic Fever" (June 28, p. 793). It is queried why, "if rheumatic fever is an infection by the *Streptococcus pyogenes*, the acute stage should not be amenable to sulphanilamide treatment." The probable explanation is that this stage is mainly a manifestation of an allergic reaction occurring in a patient sensitized to the *Streptococcus pyogenes*.—I am, etc.,

Gorseinon, Swansea,
June 30.

G. E. DONOVAN,
Medical Officer of Health.

Local Anaesthesia in Operations for Pyloric Stenosis

SIR,—The admirable article by Mr. David Levi (June 28, p. 903) establishes the main principles in the surgical treatment of congenital pyloric stenosis. There is, however, one point which is not adequately stressed in his account of the technique, and that is the employment of local anaesthesia. My own figures in a series of sixty cases are a clear indication of the value of this form of anaesthesia in this condition.

Fifty-three of these were dealt with in the children's ward of a general hospital, while the remaining seven have been operated on in nursing homes or cottage hospitals. Up to 1939 general anaesthesia was employed as a routine, and the results were far from satisfactory. In forty-one cases in this series there were thirteen deaths, a mortality of 31%, which, as Dobbs (*Lancet*, 1941, 1, 661) states, is probably an average figure for general hospitals up and down the country. My own experience bears out his statement that most of the deaths following operation were due to gastro-enteritis. In two cases infants had already returned home but were re-admitted a few weeks later on account of gastro-enteritis which proved fatal.

Since 1939 a total of 19 cases have been operated on with no mortality. The only difference between these two series has been the employment of local anaesthesia in place of a general anaesthetic. These patients have been referred to me by my medical colleagues or admitted directly under my care. Some of them had already been given a trial of "eumydrin" by the physicians, who, on the whole, have been disappointed with the results. A tendency has been noted in the more recent cases to call in a surgeon somewhat earlier than during the first series, when eumydrin was being given a trial, but apart from this there has been no distinction in the treatment in the two series, and the markedly improved results must, I feel, be attributed in great measure to the use of local anaesthesia. I have no doubt that a general anaesthetic in these cases predisposes to a subsequent gastro-enteritis.

By making a small high incision in the midline over the liver there is no danger of small intestine or omentum prolapsing out of the wound if the infant strains, while the judicious use of a teaspoonful of honey usually keeps the infant perfectly contented throughout the operation. Dobbs's suggestion that the risk of a long stay in hospital may be counterbalanced by the adverse effects of operation is answered by Levi's demonstration that operation under local anaesthesia, certainly in breast-fed infants, has no adverse effects.—I am, etc.,

Wolverhampton, June 30.

R. MILNES WALKER.

Differential Diagnosis of Contusion of the Brain

SIR,—In reply to Dr. Murdo Mackenzie's letter (June 28, p. 985), of course a psychoneurotic may complain of headache just as he may complain of pain or distress in any other organ or region of the body, but it is neither a characteristic nor a diagnostic symptom of the condition. On the other hand, severe headache in our series of cases following a definite history of concussion was the outstanding and disabling feature, often dominating the whole picture. The attitudes of the two types of sufferer to the symptom are quite different. The contused person regards his headache as itself constituting essentially the disorder, and it is the symptom for which he is most anxious to obtain relief. The neurotic, on the other hand, if he does mention headache, does so only as one symptom of a general state of distress, which he often has difficulty in describing. The contused person nearly always states that he is improving and he is hopeful; the condition of the neurotic is usually static. The condition of a contused person—at the interval of three to five months from the exciting trauma—may often be described as still subacute.

The "forgetfulness" in contusion is also quite different from the occasional inattention which leads many of us neurotic or otherwise—to leave umbrellas in omnibuses. The contused person complains of forgetfulness spontaneously as a new symptom. A housewife, for instance, finds that she must make a list of everything she goes out to buy—a thing she has never had to do before. Sufferers from this condition create the impression that they are still slightly dazed or not fully aware of their surroundings. Also they are less emotional and less concerned about their emotions than the neurotic. For these reasons it would not be characteristic for a contused person to say he "feels such a fool" for forgetting things; he is not thinking of other people. The neurotic, on the other hand, acutely sensitive to the attitude of others about him, might well make such a remark.

Each of these differences may seem small, by itself, but collectively they make two pictures which are readily distinguishable in a large proportion of the cases.—I am, etc.,

London, S.W.11, July 1.

WILLIAM A. BREND.

Paralysis accompanying Herpes Zoster

SIR.—In view of the recent correspondence in your columns regarding paresis associated with herpes, the following case would seem to be sufficiently unusual to merit mention, and serves still further to indicate the connexion between herpes and a generalized blood-stream infection.

A man aged 53, who works as a postman, has suffered from mitral disease for many years; in March, 1938, his heart began to fibrillate. This has been more or less controlled by tab. digit. pulv. for the past three years, but early in January, 1941, he had an attack of pulmonary congestion. This showed signs of clearing up by the end of the month, and on February 5 he felt better, breathing was easier, but there was still some tachycardia. On February 12 the heart sounds were steadier and the pulse rate slower, although the uneven beats of fibrillation were still present. He also complained on that day of a dull pain in the front of the right thigh, which in view of his rheumatic history I took for a myalgic pain. He returned home, and tells me that two days later (February 14) the sore area in front of the right thigh began to burn, became more red, and by the morning of the 15th blebs had begun to appear. He visited a colleague, who diagnosed herpes zoster. On the 16th a few spots appeared on his chest, face, and forehead. On the 18th he came up to see me, and showed an extensive herpetic eruption over the inner side and front of the right thigh, with a few isolated blebs below the knee and in the sacro-iliac region (L2 and L3); while, in addition, he showed a well-marked eruption resembling varicella extending over the body, limbs, and head; several of the pocks on the chest had reached the pustular stage, while those on the face were vesicular and on the forehead papular. By March 1 the herpetic vesicles had dried and some of the scabs were separating, while the varicella pocks were drying up. The patient also complained of weakness of the affected leg, the thigh muscles had lost tone, and the right knee-jerk could not be elicited. By March 10 most of the scabs of the herpes and of the varicella had dropped off, but the weakness of the knee was still marked and the right knee-jerk still absent. He developed almost complete paralysis of flexion of the right hip by the ilio-psoas, of the sartorius, and most of the quadriceps and adductors of the thigh. He was seen on April 2 by Dr. Wilfred Harris, who reports: "I took his electrical reactions myself and found complete reaction of degeneration in the vastus internus and externus and the lower half of the rectus, although the upper half of the muscle reacted normally to faradism. R.D. was almost complete in sartorius and the adductors." Massage and galvanism were given for a month and later followed up by faradism and exercises during May and June. He has made a good and gradual recovery, so that walking is now almost normal and he is taking up a light inside duty this week.

In view of Professor J. A. Nixon's remarks (July 5, p. 31) on herpes generalisatus this case seems worthy of mention, and the recovery after such a severe loss of muscular activity is very encouraging. I presume the damage to the motor fibres is at the point where the anterior roots join the posterior roots just peripheral to the ganglion.—I am, etc.,

London, W.1, July 5.

R. COVE-SMITH.

Subcutaneous Ligature of Veins

SIR.—Dr. H. S. Russell (April 26, p. 626) described a method of subcutaneous ligature of veins. For several years I have been using a similar technique for the resistant type of case. It seemed unnecessary to take up your valuable space in adding my testimony to Dr. Russell's or in amplifying his excellent article, but since then some ill-founded criticisms have been made, and I therefore thought that it might be useful to add my experiences in support of Dr. Russell's method.

I have done a considerable number of cases and have never had any complication of any kind. I do not insert the suture by means of a sewing needle, with the necessity for drawing a double thread through the tissues, but I use the hypodermic method of suturing first described, I believe, by Dickson Wright. I inject some novocain into the skin and then advance the hypodermic needle under the vein, at the same time injecting a little solution; a little more novocain is injected under the skin on the far side of the vein and a moment allowed for it to anaesthetize the skin; the needle is then pushed out through the skin; the syringe is disconnected, and a suture

is threaded through the needle like a stylet; it is usually easier to pass the suture from the point of the needle. The suture is then tied over a little piece of sterile gauze, a small elastoplast dressing is applied, and the vein is injected below this level; or the suture can be left untied for a moment and the vein injected by the empty vein technique, and then the suture is tied. It is of course wiser to have the patient lying down when passing the sutures.

A troublesome vein can be ligatured in several places and the "locks" between emptied before injecting. In this way, also, a "deep feeder vein" can be isolated and its cause of failure eliminated.

By this method I have successfully treated many cases that have been submitted to me by doctors who have stated that "injection has failed to cure these veins." I am convinced that with reasonable care the method is devoid of risk and is a valuable addition to one's technique.—I am, etc.,

Hove, July 3.

H. J. MCCURRICH.

SIR.—I have read with interest the article by Dr. H. S. Russell (April 26, p. 626) and the criticism of it by Stuart McAusland (May 17, p. 763). Subcutaneous ligature of varicose veins was first described by Velpeau and Schede and was soon given up. It was reintroduced and strongly favoured by Kocher (1916), who, in the case of widespread varicose veins, inserted 100 and sometimes more subcutaneous ligatures. Soon after Linser introduced the treatment of varicose veins by injection with sclerosing fluid, a combination of ligature and injection was employed by many surgeons.

Dr. Russell's method is harmless and painless, but it is not much more effective than injections properly done without ligature. Neither the method of injection alone nor in conjunction with subcutaneous ligature should be used in cases where a positive Trendelenburg sign is present. A positive Trendelenburg sign demands open ligature of the vein near the saphenous opening and the removal of the saphenous trunk in the thigh.

I have found that the best operation is the removal of the vein by Babcock's method followed by injection of the varices in the leg, but I should like to draw attention to a method which I employed in many thousands of cases with excellent results: The vein should be sought for in the lower part of the thigh with the patient standing upright and its position marked. The patient then lies down with the leg slightly elevated. The vein is gently exposed, using 10 c.cm. 2%, novocain. The vein is then divided between ligatures. The distal part of the vein is opened and a blunt Horrocks's or Barley's cannula is introduced and fixed in position by means of a ligature. (I use a special curved cannula with a stop-cock.) Through the cannula varying amounts of sclerosing solution may be injected depending upon the extent of the varices. I use 60% glucose in quantities up to 50 c.cm. The wound is closed by two catgut sutures and the limb bandaged firmly. This completes the simple operation, which can be easily performed with aseptic precautions in the surgery or in the patient's home. This procedure gives the only guarantee against recanalization. Recurrence is rare.

I quite agree with Dr. Russell that every effort should be made to treat varicose veins adequately, and surgeons should try to find better and still better methods of doing so.—I am, etc.,

Bradford, July 1.

NORBERT SCHICK, M.D., Vienna.

Ether Convulsions

SIR.—After reading Mr. Charles Wells's letter (June 21, p. 945), I thought it might be of interest to describe a case which came under my notice to-day in the Willesden General Hospital.

A woman of 32 had a laparotomy performed for a uterine fibroid. I used the McKesson CO₂-absorption apparatus and the anaesthetic was perfectly smooth until the time arrived for sewing up. I noticed slight spasm of the lower jaw, which did not persist, so I ignored it. However, about five minutes later spasm returned not only in the jaw but in the legs and arms. The respiration was in character like that described in Dr. Wells's letter. I was using ether in moderation with the indicator at "half." The bag was kept inflated with nitrous oxide, and the oxygen indicator stood at 4 or 6 according to the degree of cyanosis. The colour kept uniform throughout except for slight cyanosis, but this increased when the convulsions started. The pulse was of good volume, regular, and

100 to 104 in rate during the spasm. The rectal temperature was 100.4° F. There was no marked sweating of the face.

After removing the face-piece I gave chloroform, about 1/2 to 1 drachm, very cautiously in drops on a mask until the house-surgeon, Mr. Freeman, prepared 5 c.cm. of pentothal sodium. He injected 4 c.cm. as soon as possible into a vein and immediately the convulsions ceased. He gave a further 1 c.cm. after a few minutes' interval. The operation was then completed. The patient left the table with both pupils widely dilated but with normal shallow respirations.

On reaching the ward the respiration became very shallow, almost Cheyne-Stokes at intervals. On the suggestion of the house-physician, Dr. Gladstone, I gave oxygen with 5% CO₂. This after a time improved the breathing, and at long intervals the patient made a deep inspiration. All this time the pupils remained dilated, but they gradually became smaller. The pulse varied in volume but kept regular. Artificial respiration seemed to help in dispelling cyanosis while it lasted, but gradually the colour became normal after more O plus CO₂. I saw the patient about one hour later, when there was slight conjunctival reflex, but she was still unconscious. Three hours later consciousness had returned and the patient smiled and could talk.

The premedication was omnopon grain 1/3, scopolamine grain 1/150, an hour before operation.

The cases I have seen have all occurred in hot weather; fortunately none of them has been fatal.—I am, etc.,

Willesden, June 23.

C. LEONARD TRAYLEN.

SIR,—Mr. Charles Wells (June 21, p. 945) has described a case of novocain convulsions in a letter concerning "ether" convulsions. This is unfortunate because novocain convulsions are no mystery, although it seems to be insufficiently known that cocaine and all its derivatives convulse as certainly as does strychnine. On the other hand, "ether" convulsions are a great mystery still, for how are we to explain convulsions produced by a large dose of a narcotic drug?

Hyperthermia is an attractive theory, and I may be forgiven for possibly overstressing it, because it is so reasonable and so kind to keep the feverish patient cool during an operation in a heat wave. With a high temperature from a septic appendix it is not wise for the child to wear thick bed socks, be covered with blankets and mackintoshes, and to be deprived of all sweating defences by atropine.

It is of the utmost importance that the rectal temperature of all these cases be taken. As the fits are easily controlled by evipan intravenously, the abdomen should be sewn up and the rectal temperature taken when all is quiet. If it is high—and I think it is invariably—then steps can be taken to reduce it and to cool the carotid blood to stop cerebral damage and possibly a return of fits when the evipan has worn off. The fortunate thing is that evipan or pentothal is good for all fits except those due to uraemia.—I am, etc.,

A. DICKSON WRIGHT, M.S., F.R.C.S.

London, W.1, June 30.

Treatment of Gonorrhoea

SIR,—The emphasis laid on the treatment of gonorrhoea by sulphapyridine when two articles deal with that disease in the same issue of the *Journal* (June 28) is liable to create a somewhat wrong idea as to the value of the treatment.

Major MacKenna's article (p. 958) deals with gonorrhoea in men specially selected for healthy physique, and it is well known that the healthier the man the shorter is the life of the gonococcus in his system. Secondly, these men are in a position to report at once and have a rest from their daily arduous duties. Thirdly, they are at once put on an alkaline dietary. In spite of all the costly treatment outlined by Major MacKenna the relapse rate is as high as 5%.

In Dr. James Sommerville's report (p. 961) the relapses were as high as 6.66%, and complications occurred in 1.66%, while toxic symptoms occurred in 13%. These results are in striking contrast with those of Major MacKenna, but they are very instructive and therefore of value. Dr. Sommerville speaks only of alcohol as interfering with successful treatment, but he does not give any reasons why this should be. Alcohol, as is well known, tends to increase the patient's pH, which in Major MacKenna's patients was countered by the alkaline dietary. The part played by an increased pH in delaying recovery of all diseases is of great importance and deserves

the serious attention of the medical profession. The predisposition of persons to tuberculosis and acute rheumatism depends on whether their pH is increased or not, and it is hardly necessary to say that gonorrhoea in tuberculous patients is not "cured" in three days, while the tendency to complications is intensified very considerably. Good treatment can be successful only by helping the patient's constitution to re-right itself.—I am, etc.,

Swansea, June 28.

G. ARBOUR STEPHENS.

Anatomical Nomenclature

SIR,—Please allow me to suggest that it would be well for authors of medical and (particularly) surgical textbooks who, as most of them did, learnt their anatomy with the students of the last generation, to bear in mind that, wisely or unwisely, anatomical nomenclature has now largely been changed.

Studying Mr. Hamilton Bailey's excellent *Emergency Surgery*, I came across the term "cave of Retzius," for which, wishing to confirm my memory of its identity, I searched in vain the text and index of Gray's *Anatomy*, latest edition. Correspondence with the editor of the latter showed that he strongly disapproved of the retention of personal names in anatomy, and preferred the new term "retropubic pad of fat," which, of course, signifies not the "cave" but its contents. Many other examples of the same nature might be quoted. Apart from the confusion thus caused to those who, like myself, learned their anatomy twenty-five or so years ago, it seems to me (if I may venture to express an opinion) a great pity that, by the elimination of proper names, the historical aspect of anatomy should disappear. I challenge any medical man to read Fielding Garrison's *History of Medicine* without acquiring a renewed and even thrilled interest in his profession.

Meanwhile I would suggest that authors using old names should add the new ones in parentheses.—I am, etc.,

May 20.

JOHN S. MEIGHAN, M.B., Ch.B., B.Sc.,
Surgeon Lieut. R.N.V.R.

Universities and Colleges

UNIVERSITY OF OXFORD

The Weldon Memorial Prize for 1941 has been awarded to Julia Bell, M.A., F.R.C.P., Honorary Galton Research Fellow of University College, London, and member of the scientific staff of the Medical Research Council.

UNIVERSITY OF CAMBRIDGE

Owen Lydon Wade (Emmanuel College) has been awarded the Marmaduke Shield Scholarship in Human Anatomy, of the annual value of £100.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examinations indicated:

M.D.—F. C. Deller.

M.B., Ch.B.—134 N. B. Jones, 24 B. B. Evans, 23 N. O. K. Gibbon. Part III: Katharine E. Ainsworth, G. M. Ardran, W. W. Aslett, Aileen M. Barry, W. H. Berry, R. S. Cook, R. T. Davies, J. A. Donnellan, C. V. Donnelly, B. K. Ellenbogen, J. J. Ennitt, H. E. D. Flack, H. W. Forshaw, G. L. Gamble, A. J. Goldman, H. R. Gray, J. J. Hargadon, I. J. Harris, J. H. Hughes, Lillie L. Jackson, Katie H. Jones, Mair E. Jones, W. J. Jones, Mary Jordan, A. C. Kirby, C. A. Kovachich, C. C. Laird, T. E. Lamb, D. Leslie, T. B. McMurray, M. Makin, Lucy D. Meyrick, E. L. Moore, A. S. Moorhouse, P. P. Newman, J. A. B. Nicholson, J. D. F. Norman, C. N. Partington, D. E. Paterson, H. C. Percy-Hughes, G. H. Pimblett, Joan E. M. Potts, A. G. Rickards, F. S. Rickards, M. Rosenthal, C. N. Samuel, G. D. Scarrow, G. L. Shatwell, J. M. Swithinbank, W. G. Taaffe, E. Walker, C. W. Walton, A. S. Whitehead, J. K. Wilson, J. Winter, F. J. Zacharias. Part I: Mary A. R. Allan, A. S. Beadel, R. A. Blyth, W. G. Canning, J. F. Ferguson, E. N. Hugh-Jones, E. D. G. Kirkwood, Jean C. Miller, E. W. Parry, J. S. Redfern, 5 J. V. Shepherd, 5 G. H. Thomas, K. B. Thomas, Doreen M. Watt. Passed in Separate Subject: F. E. D. Griffiths (Pharmacology and General Therapeutics). Part II: G. W. Gibbs, F. E. D. Griffiths, R. B. McConnell.

1 First-class honours. 2 Second-class honours. 3 Distinction in surgery. 4 Distinction in obstetrics and gynaecology. 5 Distinction in pharmacology and general therapeutics.

UNIVERSITY OF MANCHESTER

The following candidates have been approved at the examinations indicated:

M.D.—P. R. Evans (by thesis), J. A. Hobson (by examination).
M.B., Ch.B.—E. P. Abson, R. G. Ball, J. Ball, E. A. Cachia, D. M. Coates, B. O. Dowdell, B. I. Eames, Jeanne M. Edwards, F. Feinmann, A. Glass, J. C. Greenwood, P. G. Griffiths, E. G. Hall, Frances A. Hepburn, Marcet Jacques, R. P. Jepson, Susanne M. Lempert, D. C. Little, F. S. Mooney, T. E. Parry, *S. S. Rose, J. Thompson, Vera Waime, F. R. Wille, H. L. Wise, B. Wolman, P. B. Woolley. *Part I (Forensic Medicine and Hygiene and Preventive Medicine):* Alice Akred, G. Ashe, A. N. Ashworth, Shirley G. Barrett, Pauline Blockey, H. Bolton, H. A. Boydell, D. M. Brierley, W. E. Broughton, Kathleen M. Brown, P. Cliff, J. G. Coburn, D. G. Crawshaw, Betty J. Dakin, Sheila Egan, D. Eglin, C. J. L. Elsdon, Nora F. M. Falk, S. Falk, A. I. Goodman, S. Grace, R. Greenwood, N. Harris, K. Heap, Mary W. P. Huddart, Esther Jackson, W. H. Lowdale, R. L. Lunt, C. W. Marsden, R. W. T. Mason, Ann L. Pinson, Ethel J. Samuel, Eileen T. Sloane, H. F. Smith, O. C. Sueden, D. Sutton, M. Swerdlow, R. H. Townsend, Margaret Wade, A. E. Wall, H. C. Warrington, J. Whewell, J. K. Wright.

* Second-class honours. † Distinction in medicine.

‡ Distinction in forensic medicine.

UNIVERSITY OF ST. ANDREWS

At a graduation ceremony on June 27 the following medical degrees were conferred:

M.D.—R. Y. Dunlop, Jean L. Halkum.

M.B., Ch.B.—*Nancy Young, *K. G. Lowe, *A. W. K. Main, *E. L. McQuitty, *Lactia J. W. Douglas, *Anne M. Wood, *Gwendoline M. Sturrock, Mary O. Adams, Margaret C. Barnett, Elizabeth S. Bayne, S. C. Chatterji, F. E. Clinick, A. Everard, Joyce M. Fleming, R. S. Flynn, J. O. Forfar, Philippa E. Gaffikin, Sheila Graham, J. S. Law, A. MacKenzie, R. S. MacKenzie, A. MacLean, F. A. Macrae, J. M. S. Manson, N. Paton, J. M. Robertson, Kathleen Robertson, Constance F. Ross (*née* Reed), A. E. D. Sanjani, Agnes G. Swales (*née* Brough), K. A. Swales, A. K. Tulloch.

The William Low prize for the most distinguished student was awarded equally to Nancy Young and K. G. Lowe.

* With commendation.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Election to the Council

On July 3 four Fellows were elected into the Council to fill the vacancies caused by the retirement in rotation of Professor A. H. Burgess, Mr. H. S. Souttar, and Mr. V. Zachary Cope, and by the death of Mr. R. C. Elmslie. The result of the poll was as follows:

	<i>Votes</i>
ARTHUR HENRY BURGESS (Manchester)	608
HENRY SESSIONS SOUTTAR (The London Hospital) 604	
VINCENT ZACHARY COPE (St. Mary's Hospital)	528
ERNEST FREDERICK FINCH (Sheffield)	492
Philip Henry Mitchiner (St. Thomas's Hospital)	480
Sir Harold Delf Gillies (St. Bartholomew's Hospital)	467
Reginald Martin Vick (St. Bartholomew's Hospital)	429

In all 1,097 Fellows voted; in addition seven votes were found to be invalid. Professor Burgess, Mr. Souttar, and Mr. Cope are all elected for the full period of eight years, and Mr. Finch acts as substitute member for the late Mr. Elmslie until July, 1946.

SOCIETY OF APOTHECARIES OF LONDON

The following candidates have passed in the subjects indicated:

SURGERY.—J. A. Dodds, M. El Badri, D. A. Ogden.

MEDICINE, PATHOLOGY, AND FORENSIC MEDICINE.—G. R. Boyes, D. A. Ogden.

MIDWIFERY.—D. A. Ogden, J. M. Macdonald, J. Mason, Le R. D. Miller.

The diploma of the Society has been granted to D. A. Ogden.

Three additional Sigmund Freud fellowships for psychoanalytical training have been announced by the Boston Psychoanalytical Institute. The fellowships will begin in September, 1941, and are open to graduates of recognized medical schools who have had at least one year's work in general hospital training and two years' work in psychiatry.

Obituary

SIR FREDERIC STILL, K.C.V.O., M.D.,
F.R.C.P., LL.D.

Physician Extraordinary to the King; Emeritus Professor of Diseases of Children, King's College, London

George Frederic Still was born in London in February, 1868. From Merchant Taylors' School he went up to Caius College, Cambridge, and thence to Guy's Hospital. At Cambridge he gained first-class honours in the Classical Tripos and was Winchester prizeman. At Guy's he was house-physician in 1894 after taking the M.B., B.Ch. degrees, and in the same year won the Murchison Scholarship of the Royal College of Physicians of London. Early in his career Still decided to specialize in medical diseases of childhood, and he was appointed assistant physician at the Hospital for Sick Children, Great Ormond Street. In 1896 he was awarded the Cambridge M.D. for his thesis on "A Special Form of Joint Disease met with in Children." The substance of this appeared in the first edition of Allbutt's *System of Medicine*, 1897, Vol. III. It was a short article of five pages, but it introduced to the medical world a form of disease previously unrecognizable which became known, as it is to-day, as Still's disease. He defined the condition as a chronic progressive enlargement of joints associated with enlargement of lymphatic glands and spleen, coming on before the second dentition.

In 1899 Dr. Still was appointed physician for diseases of children at King's College Hospital, the first hospital with a medical school to establish a special department for diseases of children, and in 1906 King's College, London, made him its first professor of diseases of children. At the Royal College of Physicians, of which he became a Fellow in 1901, Still was Goulstonian Lecturer (1902), Lumleian Lecturer (1918), FitzPatrick Lecturer (1928 and 1929), and Censor (1932-3). For three years he was the chairman of the Medical Board at King's and a valued member of the committee of management of the hospital. In 1905 he joined Sir James Goodhart in preparing the fifth edition of his former chief's well-known *Diseases of Children* and continued as co-editor until 1909, when he published on his own account a textbook, *Common Diseases of Children*. This was based on lectures he had given at King's College and Great Ormond Street Hospitals, with considerable additions. His theme was the everyday and the commonplace diseases which bulk most largely at a children's hospital and in the routine work of the private practitioner. The book, being very practical, met with immediate success and reached a fifth edition in 1927. He contributed to Allbutt and Rolleston's *System of Medicine*, 1907, Vol. III, an article on congenital hypertrophy of the pylorus. It was a concise and clear consideration of a disease first described by Samuel Gee, which, thanks in part to his own observation, was being recognized much more often than in earlier years. In 1919 he contributed to the Osler Birthday Volumes an article on "Some Seventeenth Century Writings on Diseases of Children," in which he paid tribute to the value of books by Francis Glisson and Walter Harris, physician to Charles II, and Thomas Sydenham's work on

chorea was of course not forgotten. The subject of his FitzPatrick Lectures before the Royal College of Physicians was "The History of Paediatrics in the XVIth and in the XVIIth and XVIIIth Centuries." In them he amplified his paper in the Osler Birthday Volumes, but even then he found that there was much more in the subject than two lectures could satisfactorily encompass, and in 1931 there came from his scholarly pen *A History of Paediatrics*. This surveyed progress in the study of disease of the child up to the end of the eighteenth century, with a wealth of reproductions of title-pages and illustrations from old books and portraits. He was elected first president of the British Paediatric Association, and similar societies in the United States and Canada made him an honorary member. Very interesting lectures given by him at Birmingham in 1927 under the Ingloby Trust dealt with "Place-in-family as a Factor of Disease." A short paper on "Infantile Scurvy: Its History" appeared in the *Archives of Disease in Childhood* for August, 1935, with other articles bearing on the importance of Thomas Barlow's discovery in 1883 of the true nature of that disease. This special number of a journal with which Still had close connexion as chairman of its Editorial Committee was produced in honour of Sir Thomas Barlow's ninetieth birthday. Dr. Still's contribution indicated how near earlier writers had got to the truth and yet how they missed the essential feature of the deficiency nature of the disorder. He kept up his interests in classics, and in 1931, on the centenary of King's College Medical School, wrote in Latin verse "Carmen Scholae Medicinae," which was set to music and sung at the celebrations. In 1932 at the Centenary Meeting of the British Medical Association he was president of the Section of Diseases of Children, and next year presided over the International Paediatric Congress held in England. His long period of fruitful service to Great Ormond Street Hospital was recognized by election as consulting physician. He had also been for many years consulting physician to the Infants' Hospital, Vincent Square, to Dr. Barnardo's Homes, and to the Society for Waifs and Strays. The National Association for the Prevention of Infant Mortality had the benefit of his chairmanship for twenty years.

In 1934 Dr. Still was awarded the Dawson Williams Prize (founded in memory of the late Editor of the *British Medical Journal*) in honour of his work for sick children. When he retired from hospital duties King's College and its Hospital elected him emeritus professor and consulting physician, and a widely supported project was set on foot to pay tribute to "a great physician and lover of children." This took the form of a presentation portrait by Gerald Kelly, R.A. (reproduced on the preceding page), and the endowment of a "Dr. Still Cot" at King's College Hospital.

Sir Frederic Still was created K.C.V.O. among the Coronation Honours of 1937 in recognition of his life-long devotion to the welfare of children and his personal services to the Royal Family. In the same year he became Physician Extraordinary to the King, and was elected an Honorary Fellow of the Royal Society of Medicine. The University of Edinburgh also honoured him with the degree of LL.D.

A correspondent writes:

Handsome of feature, slight of build, with a grave courtesy all his own, George Frederic Still warmed towards a child, and if its mother tried him he bore with her in a spirit of fortitude and forbearance. His own widowed mother was his dearest friend and they lived together until her death at an advanced age broke the happy union. It was charming to see them on their way to church on Sunday, she supported on his arm, he in spruce frock-coat holding the Prayer Book and Hymnal. The waiting-room at the old house in Queen Anne Street had a grand assortment of toys to beguile or soothe the young people before their turn came to enter the presence of the doctor with the quiet manner and sweet smile. Many of us

remember him as a businesslike chairman, graciously but firmly keeping his committee to the point. Dr. Still never flinched from duty, and his life was filled with tender thought for all sick or unhappy children. Now he has gone to his rest, and we are the poorer; but the influence he wielded is not cut off by death.

J. R. DICKSON, O.B.E., M.B., C.M.

Secretary, Trinidad and Tobago Branch, B.M.A.

A correspondent sends the following appreciation, which supplements the obituary notice published on June 28.

John Rhodes Dickson, whose sudden death on April 8 is deplored by everyone in Trinidad and Tobago and most of all by his colleagues, was born seventy-four years ago at Arouca, Trinidad, where his father, the Rev. W. F. Dickson, was minister of the Presbyterian Church. He was educated at the Queen's Royal College, Port of Spain, where he won an Island Scholarship in 1884, and at Edinburgh University. He joined the Government Service in 1891; and after serving as assistant surgeon at the Colonial Hospital and holding acting appointments in country districts, he decided to specialize in public health work. It is largely due to his efforts that the Government came to recognize the value of public health, and the Public Health Service, which is now full grown and working well, is the result of Dickson's constant and untiring efforts. He was the first pathologist and bacteriologist for the Colony, and was also largely responsible for checking epidemics of yellow fever and bubonic plague in 1907-8. These diseases have never reappeared. He was in England on leave in 1914 and was taken by the War Office and attached to the R.A.M.C. for six years. On his return to Trinidad he was appointed Deputy Surgeon-General and Senior Medical Inspector of Health for the Colony. He frequently acted as Surgeon-General. He retired from the Service in 1930 and was awarded the O.B.E. He was then, appointed lecturer to the Imperial College of Tropical Agriculture, which post he held until 1939. After Dr. K. S. Wise, the Surgeon-General, retired the Government showed their appreciation of Dickson's sterling qualities and appointed him chairman of the Bruce Stephens (Charitable) Trust. For years he had been vice-president and mainstay of the Child Welfare League. He had been a useful member of the Council of the Medical Board of Trinidad and Tobago and was its vice-president.

Besides these activities, enough for any one man, Dickson must be remembered as the one who worked hardest at reviving the almost defunct Branch of the B.M.A. and with zeal and unceasing labour as Branch Secretary. He attended the annual meeting at San Fernando on April 5. He seldom missed the Annual Meeting of the B.M.A. when in England. Island-wide tribute was paid to the passing of a distinguished son of Trinidad who had always kept in the forefront of his thoughts and actions measures for the advancement of public health, child welfare, and alleviation of distress, and the welfare of the profession. A lack of show, characteristic of Dickson, hid the true extent and range of his work and sympathies.

Dr. K. S. Wise writes:

As we were, for two years, very closely associated in the administration of health affairs in Trinidad, I am glad to pay my tribute to Dr. Dickson, whom I regarded very highly as a professional colleague and even more so as a friend of exceptional charm and character. He was a man to whom his word was often more than his bond. To assign him some important duty was to know that it would be well and thoroughly completed with a conscientious regard for each and every detail as well as a careful consideration of the broad and fundamental principles. This is well illustrated by his early realization that success in the administration and efficiency of public health measures required not only a high degree of technical skill but also a well-trained local personnel and a liberally instructed public. - Much of his earlier professional career was spent in the organizing and effecting such training and public instruction. His efforts certainly induced in the public mind a healthy sensitiveness to sanitary matters in general and brought into being a valuable and experienced body of associated medical personnel. His success in this hitherto virgin field in the early years of this century are well known to those familiar with health affairs in Trinidad. Needless to add, this shining example had its effect beyond the confines of Trinidad in other areas in the West Indies. With the passing of Dr. Dickson the Island of Trinidad has lost a skilled professional colleague, a generous and kindly friend, and an unselfish, public-spirited citizen.

W. PARRY MORGAN, M.D.

Lecturer in Bacteriology, Welsh National School of Medicine

We regret to announce the death on June 14 of Dr. W. Parry Morgan, well known as a bacteriologist in Cardiff, where he held important public and academic posts.

William Parry Morgan was a native of Cardiff and most of his working life was spent there. From the University College of South Wales and Monmouthshire he entered Clare College, Cambridge, where he won the Lady Clare scholarship and was 16th wrangler in the Mathematical Tripos of 1898; he went on to study medicine at St. Mary's Hospital with a university scholarship. Having taken the degree of B.Sc. Lond. and the M.R.C.S., L.R.C.P. diplomas in 1904, he served as house-surgeon, house-physician, and resident obstetrical officer at St. Mary's, took the M.A. and B.Ch. at Cambridge in 1906, and the M.B. in 1908; for his M.D. thesis in 1917 he was named *proxime accessit* for the Horton Smith prize.

From 1908 to 1914 he held the post of assistant in the department of therapeutic inoculation at St. Mary's Hospital, but this was interrupted by a year's work in South Africa as research bacteriologist under the Witwatersrand Native Labour Association, for whom he prepared jointly with Sir Almoth Wright in 1913 a report on pneumonia. During the last war Dr. Parry Morgan held a temporary commission as captain in the R.A.M.C., working mainly in laboratories. He was then appointed pathologist and bacteriologist at the Glamorgan County and Cardiff Public Health Laboratory and lecturer in bacteriology in the Welsh National School of Medicine. He was the author of articles on the technique of artificial pneumothorax in the treatment of pulmonary tuberculosis, published in the *Lancet* in 1914 and the *Quarterly Journal of Medicine* in 1917; and a controversial paper read to the Pathological Section of the Royal Society of Medicine on the treatment of wound infections appeared in the *British Medical Journal* of May 13, 1916.

The death on June 13 at his home in Buckinghamshire of Dr. GEORGE EDWARD TWYNAM at the age of 53 removes one of the few remaining links with the early pioneers of Listerian surgery. Educated at University College Hospital, where he shared lodgings with three other students, one of whom was Victor Horsley, he qualified as M.R.C.S. in 1880 and took the L.R.C.P. in 1881. After doing a house appointment at his own hospital he obtained a post as house-surgeon in Sydney. When he arrived there he found the medical profession much interested in what they had heard and read of Lister's discoveries; but few of them had first-hand knowledge of the new antiseptic technique, and they welcomed a young surgeon who could show them how things were being done in London. The result was that Twynam soon found himself elected to the honorary staff of the Prince Alfred Hospital, Sydney, and later became lecturer on clinical surgery at the university. He was a successful general practitioner and consulting surgeon in Sydney for several years, but eventually returned home for private reasons. He then started in general practice in South Kensington, where he was well known for many years and was both popular with and respected by his colleagues. Some years ago he retired, at first to Sevenoaks and later to Buckinghamshire. He retained his physical vigour in marked degree: when well turned seventy he was accustomed to take country walks of thirty miles or even more, purely for recreation. He had many recollections of Sir Victor Horsley as a young man: one of Horsley's foibles which Twynam used to recount was his persistent refusal to pass his fellow students the mustard pot at meals; he held that mustard was an artificial stimulant to the gastric mucosa, as harmful as alcohol. You could get up and fetch it for yourself if you wished, but he wouldn't have act or part in the matter by passing it across the table.

The death of Dr. DOUGLAS DENT MALPAS has broken another link with Victorian life and manners. We lose thereby one of our most worthy colleagues in the outer world of general practice, where the limelight seldom penetrates but the traditions of the profession are upheld and its influence for good is felt both by patients and by the community. Son of the Rev. Henry Malpas of Bristol, Malpas studied medicine at Guy's, Aberdeen, and Paris, and, after qualifying as M.R.C.S. Eng. nearly 65 years ago, took his

M.B., C.M. at Aberdeen in 1878 and M.D. in 1881. For over thirty years he was in consulting practice among the British at Biarritz, where his professional skill and character of mind and heart won for him a position of considerable influence. He attended many distinguished visitors there, including King Edward VII, in a consultant capacity. After qualifying, he travelled in what is now called the Middle East and round the world for some eighteen months with a wealthy patient, on the verge of a mental breakdown, for whom he and his wife made a home for thirty years—a severe test of Christian friendship. He was intensely religious, one of the quakerlike Plymouth Brethren, and maintained a keen interest in evangelistic work throughout his life. Distinguished in appearance, dress, and manner, he was essentially grave and serious, a blend of the Senator and Puritan. He retired to Boscombe during the last war, and died there on June 9 last in his ninetieth year. In 1886 Malpas married Sarah Culme Shepherd, who predeceased him. Their eldest son died of cerebrospinal meningitis in the Crystal Palace epidemic while on active service during the last war. The surviving son, Dr. Douglas Duncan Malpas, is in radiological practice at Bournemouth.

Medical Notes in Parliament

Pharmacy and Medicines Bill

In the House of Commons on July 5 MR. ERNEST BROWN moved the Second Reading of the Pharmacy and Medicines Bill, which, he said, repealed the Medicine Stamp Duty in accordance with a promise given by the Chancellor of the Exchequer last April. Pointing out that the stamp duty yielded about £800,000, and the licence duty about £40,000, he said that the tax had become difficult to collect, if not unworkable. The same medicine might be sold in one shop without regard to tax, while in another shop tax would be paid. None of the exceptions was justified on grounds of public health, and the whole basis on which the duties rested was defective. The result of the application of the Purchase Tax to medicines at 16½% was that the estimated yield would be about £3,000,000 a year, or nearly four times the present annual yield of the medicine duties. The continuance and maintenance of the chemist's profession were essential to the welfare of the community, and the trading interests had reached an agreement on the various points concerned. The agreement was provided for in the Bill and was a solution which would safeguard the interests of chemists. There was no desire to interfere with the interests of legitimate herbalists.

SECRET MEDICINES AND ADVERTISEMENTS

The Bill regulated the trade in medicines and, in regard to secret remedies, the course had been chosen which was most likely to help. The brutally scandalous age of patent medicines was now largely a matter of the past, but in the present state of the law an opportunity still existed for the unscrupulous to trade on the fears of the uninformed and credulous. Any qualified person would in future be able to tell the value of any medicine and to advise the user accordingly. The only kind of medicines in which disclosure of ingredients was not required would be those supplied to individual persons and prescribed according to their needs, such, for example, as a mixture made up on a doctor's prescription.

Advertisements dealing with remedies for certain serious diseases or with articles for procuring abortion would in future be prohibited. Legislation of this kind already existed prohibiting the advertisement of articles recommended for the treatment of venereal diseases and cancer. The present Bill would prohibit the advertisement of such remedies as those for Bright's disease, cataract, diabetes, epilepsy or fits, glaucoma, locomotor ataxy, paralysis, and tuberculosis. The basis for this list was the report of the Select Committee of 1914, and the diseases had been selected because, like cancer and venereal disease, they were all of a serious nature, and were susceptible of alleviation, if not cure, by normal methods of treatment, and because it was dangerous in each case to delay seeking treatment by resorting to quack medicines. The Bill also made minor amendments to the Pharmacy and Poisons Act, and was the first step in the journey on the road to reform.

LONG-OVERDUE MEASURE

In the debate which followed, Mr. BEVERLEY BAXTER, speaking as a member of the Committee of 1937, said that although the Bill looked very innocent and constructive, it had a tendency to place monopoly powers in the hands of the British Medical Association, which was a very reactionary institution. There was a tendency to ban things too much. He would rather have a system of inquiry into and judgment on the efficacy of the various remedies. Mr. J. GRIFFITHS said that the only way to prevent the exploitation of the poor was by providing a real State Medical Service.

Prof. HILL extended a warm welcome to the Bill, which, he said, was long overdue. We had been too respectful and tolerant of vested interests in the past, which had exploited the sick and suffering, and it was time we realized that, *laissez faire* in this matter led to cruel scandals. He complimented the Minister of Health on his courage in bringing in the Bill. Mr. H. STRAUSS said that the Bill would still permit the kind of advertisement designed to produce a sense of ill-health. The best way to stop these advertisements would be to have distinguished doctors broadcasting on the value to be placed on the advertising of some kinds of medicine.

Sir ERNEST GRAHAM-LITTLE supported the Bill, but regretted that so little was proposed to be done by it. A larger quantity of medicines was consumed by the people of this country than anywhere else in the world. It was not good that persons should dose themselves without check. One reason for the immense increase in the use of medicines was the power of the Press. He did not think that the proposal for restricting advertisements of medicines went far enough.

Mr. R. T. DAVIES said that the Bill did not deal with advertisements of surgical appliances, such as aids for the deaf, which were often sold at high prices. He asked if the word "advertisement" covered speeches by quacks in the market-places as well as the printed word.

STATE REGISTER OF PROPRIETARY MEDICINES

Mr. WAKEFIELD urged that the Bill did not go far enough in the control of proprietary medicines, but hoped that it was only a beginning. Many persons, he said, felt that the State should take a greater responsibility for the proprietary medicines now offered for sale. The goal to be aimed at should be, if a medicine were valuable and the claim made for it reasonable, the State should authorize its sale. If the medicine were banned it should be on the responsibility of the State entirely to prohibit the sale. That would mean the introduction of a State register of proprietary medicines.

Sir FRANCIS FREMANTLE expressed regret that it had not been found possible to include advertisements of surgical appliances in the Bill. The Bill made a beginning in the stopping of fraud and would help toward the promotion of truth in the application and use of medicines. He regretted that the Bill did not compel disclosure of the quantity of the component parts of the preparations. The gibes which had been made against the British Medical Association were most unfair and unjust. He expressed the hope that in a few years' time a useful amending measure would evolve from the experience gained by the working of this Bill. It was ridiculous to describe the Bill as hasty legislation. Captain ELLISTON said he hoped to put forward amendments in committee for the enforcement of its provisions. The quantity as well as the nature of the substances in any preparation ought to be disclosed.

Miss HORSBRUGH, replying to the debate, denied that the Bill prejudiced the little man compared with his bigger competitor. Herbalists, if they were not carrying out the law, would be shut down after the Bill had passed. The only difference would be that they, like other people, would be compelled to put the ingredients of the mixtures they sold on the bottles or packets. No impediment would be placed on the sale of such drugs as insulin; the object of the Bill was not to prevent things being sold but to let the public know what they were buying. The Bill did not profess to deal with advertisements as a whole, but only certain classes of advertisements. The fact that the ingredients of a remedy had to be disclosed would, in many cases, stop what might be a ramp.

The Bill was read a second time.

The Milk Situation

In the House of Lords on July 1 Lord TEVIOT called attention to the present agricultural policy of the Government, especially in regard to the best treatment of the land to produce the maximum quantity of healthy food.

Lord DAWSON said that the present consumption of milk was probably greater than at any other period. It had contributed in no small measure to the good health of the people, notwithstanding the rationing of staple foods and the inevitable wear and tear of the times. While the consumption was increasing, however, the production of milk was decreasing. We wanted to prevent illness and maintain health, and for that milk was necessary. Last winter we were fortunate in the matter of epidemic illness, but we could not be sure that we should have equally good fortune in the coming winter. We must, therefore, maintain our dairy herds at almost any cost. We could curtail meat and even cheese so long as there was sufficient milk. Milk was the keystone of the nutritional arch, and if we interfered with that keystone we should weaken the whole fabric.

The problem of milk production was concerned with winter feed for dairy cattle. If food production was to be maintained in the coming winter, dairy cattle must have priority of home-grown feeding stuffs and the balance which they needed above these must be obtained by importing feeding stuffs. The only alternative, if we could not do something to stop the diminishing production of milk by giving real priority to dairy herds, was to reduce the consumption of milk in this country. That would, however, inevitably entail risks in the coming winter and might even be fraught with danger. He hoped that a compulsory system of milk rationing, with all its attendant evils, could yet be avoided.

The Services

BIRTHDAY MEDICAL HONOURS

The names of the following members of the medical profession in the Services appear in the Birthday Honours List in a Supplement to the *London Gazette* published on July 1.

K.B.E. (Military Division)

HAROLD EDWARD WHITTINGHAM, C.B.E., M.B., Ch.B., F.R.C.P., Air Marshal, Royal Air Force. Honorary Physician to the King. Director-General of Medical Services, Air Ministry.

C.B. (Military Division)

CYRIL VERITY GRIFFITHS, D.S.O., M.R.C.S., L.R.C.P. Surgeon Rear-Admiral, R.N. Honorary Physician to the King. Deputy Medical Director-General, Admiralty.

ROBERT CECIL PRIEST, M.D., F.R.C.P. Major-General, late R.A.M.C. Honorary Physician to the King. Consulting Physician to the British Army and Professor of Tropical Medicine, Royal Army Medical College.

O.B.E. (Military Division)

ABANI MOHAN CHAUDHURI, M.B., F.R.C.S. Major, I.M.S. EDWARD CAWDRON CORDEAUX, D.S.O., M.B., B.S. Acting Captain, R.N.

RONALD GRANT DINGWALL, M.B., Ch.B. Surgeon Lieutenant-Commander, R.N.

WILLIAM RALSTON DUNCAN HAMILTON, M.B., Ch.B. Major (Temporary, Lieutenant-Colonel), R.A.M.C.

THOMAS MADILL, M.B., B.Ch. Surgeon Commander, R.N.

M.B.E. (Military Division)

GEORGE JAMESON CARR, M.B. Lieutenant (Temporary Major), R.A.M.C.

Mentions in Dispatches

Surgeon Lieutenant John Fawcett Hughes, R.N., Surgeon Lieutenant Frederick Bagot, R.N.V.R., Surgeon Lieutenant Robert Lewis Ferguson, R.N.V.R., Temporary Surgeon Lieutenant Richard Constant Ponder, R.N.V.R., and Temporary Surgeon Lieutenant John Heaton Simpson, R.N.V.R., have been mentioned in dispatches for good services in the last six months or more of war.

R.A.F. AWARD

The King has awarded the Air Force Cross to Flight Lieutenant William Kilpatrick Stewart, R.A.F.V.R.

CASUALTIES IN THE MEDICAL SERVICES

ROYAL ARMY MEDICAL CORPS

Temporary Major HUGH EMMYS BONNELL lost his life by enemy action in May at the age of 35. He was educated at the University College of South Wales and Monmouthshire and at King's College Hospital, qualifying M.R.C.S., L.R.C.P. in 1931. He was chiefly interested in pathology and held appointments in this specialty at King's College Hospital, Manchester Royal Infirmary, and the Royal East Sussex Hospital, Hastings, before becoming pathologist to the East Ham Memorial Hospital and consulting pathologist to the Runwell Hospital, Wickford.

Prisoner of War

Captain Eric Davey Trounce Lewis.

EPIDEMIOLOGICAL NOTES

Infectious Diseases for the Week

Enteric fever and dysentery, which in recent weeks have been on the increase in England and Wales and in Scotland, have declined in both countries during the week under review. Cerebrospinal fever has increased slightly and, in England and Wales, diphtheria and whooping-cough to a greater extent. Acute poliomyelitis, which tends to appear in June, is less than one-half as frequent as in the corresponding week of 1940.

Cerebrospinal Fever

For the second week in succession the incidence of cerebrospinal fever has exceeded that of the corresponding period of last year; it is present in over two-thirds of the administrative areas of England and Wales, but only in five were more than 9 cases notified—namely, Lancaster 34 (Blackpool 2, Liverpool 11, Manchester 2, Rochdale 2, Nelson M.B. 3, Whiston R.D. 2, and 1 each in Bolton, Oldham, Southport C.B., Ashton-under-Lyne M.B., Brierfield U.D., Denton, Fulwood U.D., Heywood M.B., Huyton with Roby U.D., Leigh M.B. and Poulton le Fyde U.D., Warrington R.D.); Yorks, West Riding 21 (Sheffield 8, Huddersfield 2, Leeds C.B. 2, and 1 each in Barnsley, Bradford, Rotherham C.B. and R.D., Wakefield, York, Adwick-le-Street U.D., Brighouse M.B., Harrogate M.B., Swinton U.D., Sedburgh R.D.); London 13 (Bethnal Green and Hammersmith 2 each, Camberwell, Fulham, Holborn, Islington, Lambeth, Lewisham, St. Pancras, Poplar, Stepney 1 each); Gloucester 12 (Bristol 8, Gloucester C.B. 1, R.D. 1, Cheltenham 2); Middlesex 12 (Enfield U.D. and Hornsey M.B. 2 each, and 1 each in Feltham U.D., Friern Barnet U.D., Hayes and Harlington U.D., Hendon M.B., Tottenham M.B., Twickenham M.B., and Wembley M.B.); Glamorgan 10 (Cardiff 2, Swansea 1, Caerphilly U.D. 1, Gelligaer U.D. 1, Neath M.B. 2, Ogmore and Garw U.D. 1, Pontardawe U.D. 2). In Scotland fifteen counties or burghs were affected, chiefly, Glasgow 15, Edinburgh 7, and Ayr county 5.

Dysentery and Enteric Fever

Dysentery appeared in England and Wales in eighteen areas and enteric fever in twenty-six, as against twenty-one and twenty-five respectively in the previous week. The former was fairly widely distributed in Lancaster. The paratyphoid fever epidemic in Birmingham and surrounding district, referred to in these columns last week, continues. In Lancaster the 32 dysentery cases notified occurred in Blackburn 4, Liverpool 1, St. Helens 3, Lancaster M.B. 1, Blackburn R.D. 10, Preston R.D. 3, Warrington R.D. and Whiston R.D. 5 each. More than one-half the cases of enteric fever notified in the whole country belong to the Birmingham outbreak—namely, Warwick 43 (Birmingham 24, Coventry 5, Solihull U.D. 11, Sutton Coldfield M.B. 2, Meriden R.D. 1); Worcester 11, all in Bewdley M.B.; Stafford 6 (Smethwick 3, Stoke-on-Trent, Aldridge U.D., and Lichfield M.B. 1 each). The only other counties affected to any extent were Leicestershire 12 (Leicester 8, Barrow-upon-Soar R.D. 2, Billesdon R.D. 2), and Somerset 12 (Taunton 8, and 1 each in Wellington U.D., Bathavon R.D., Chard R.D., and Long Ashton R.D.). In Scotland there were 25 cases of paratyphoid B fever, of which 13 were in Dundee; and 5 of typhoid (3 in Glasgow and one each in Angus county and Ayr burgh).

INFECTIOUS DISEASES AND VITAL STATISTICS

No. 24

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended June 14.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland. Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Medical News

The British Institute of Philosophy announces that a short address, entitled "The War and Philosophy," will be delivered by Sir W. David Ross, Provost of Oriel College, Oxford, at University Hall, 14, Gordon Square, London, W.C.1, at 1.45 p.m. on Tuesday, July 22. Cards of admission can be had from the Director of Studies at University Hall.

The summer meeting of the Association of Clinical Pathologists will be held at Cambridge on Saturday, July 19. The scientific part of the proceedings will open in the University Department of Pathology at 10 a.m., and the day's programme will close with dinner in Trinity Hall at 7 p.m. A number of papers and demonstrations have already been promised. Members who notify their intention of attending will receive information as to accommodation and final arrangements for the meeting from Dr. C. H. Whittle, Brookfield, Trumpington Road, Cambridge.

The following medical promotions in and appointments to the Order of the Hospital of St. John of Jerusalem were announced in the *London Gazette* of June 27. As Knights: Lord Horder, G.C.V.O., Major-General the Hon. Sir E. Fiset, C.M.G., D.S.O., V.D., Lieut.-Colonel I. Fraser, S. McCormac. As Commanders: Captain R. Williams, G. B. Peat, Colonel W. W. White, V.D., Major-General Sir Gordon G. Jolly, K.C.I.E., I.M.S., Majors S. Copley and A. T. Smith. As Officers: J. E. Dovey, Colonel J. Pratt-Johnson, M.C., V.D., Captain G. W. C. Bissett, J. A. Corrigan, H. A. Creighton, A. G. Morris, E. W. Stewart, J. Ferguson, H. B. Pierce, A. M. Robertson, J. Wells, Lieut.-Colonels J. W. Tice, F. A. Barker, C.I.E., O.B.E., I.M.S. (ret.), and W. S. C. Copeman, R.A.M.C. As Associate Officer: B. W. Advani. As Serving Brothers: C. R. Hoskyn, D. J. Nicol, H. Fallows, J. L. Lewthwaite, C. Lundie, B. W. MacDonald, C. Marks, J. Gillan, J. R. Larson, M. V. Roberts, E. L. Davies, H. Lloyd. As Associate Serving Brother: S. J. Hoffman. As Serving Sister: Mary I. Place.

Profs. Henrik Dam the biochemist, and George de Hevesy the chemist, of Copenhagen have been appointed lecturers at Harvard University for the current academic year.

A central health institute has been founded in Turkey. It will contain a school for public health and an institute of hygiene.

The New York State department of health reports that 434 typhoid carriers, exclusive of those in State institutions, were under supervision in Upstate New York at the close of 1940. Thirty-seven new cases were added during the year.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS of their articles must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be addressed to the Secretary.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES: EDITOR, *Aitiology Westcent*, London; SECRETARY, *Medisecia Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Obstinate Oedema

"X. Z." asks for advice in the case of a man of 45 with retinitis pigmentosa, six toes on each foot, a mental defect; he is not obese but has oedema of both legs, and his underclothes tend to fall into small holes. At times the oedema extends and becomes very marked in the eyelids and around the neck and scrotum and penis. There is no albuminuria; blood pressure 140/86. The oedema does not respond to caffeine or mercurial diuretics or to increase or decrease in salt or protein. He refuses hospital investigation.

Ragged Finger-nails

"R. S. M." writes: "F. R. S." may be interested in the few points I can add to his description (June 21, p. 952). The patients in my three cases, aged 50 to 60, are closely related, active, healthy people without digestive or cardiac troubles. All originated before food restrictions and have not grown worse since. The fingers very often "go dead." This is followed in one case by chilblains, often involving the nail-beds. When the inflammation subsides the nail is partially detached from its bed, and as it grows becomes longitudinally ridged and brittle. In a second case the nails are almost lost; in the third mild persistent infection is superadded. Toe-nails are normal. Calcium and parathyroid are very useful in controlling the chilblains.

Income Tax

Purchase of Additional Car

"J. M." has a car which requires extensive overhaul and spare parts will be difficult to obtain. In the meantime he has obtained a similar second-hand car and is using it as a spare car.

* * The cost of the additional car ranks as capital expenditure

* and, of course, depreciation allowance is due in respect of it. On the other hand spare parts represent ordinary maintenance and their cost can be charged against current earnings. If one of the two cars is scrapped and parts of it used for repairing the other, a rather difficult situation will arise. It is thought that in such circumstances the inspector of taxes may agree to allow as a deduction the market price of the parts so used.

LETTERS, NOTES, ETC.

The Unburned Cornea

In one of Jules Verne's books the hero has his eyes put out with red-hot irons, but a film of tears over the cornea is turned into steam, and when the lid burns finally recover it is found that the cornea, thanks to this protective layer, has not been burned at all. At the June meeting of the Section of Ophthalmology of the Royal Society of Medicine Mr. T. M. Tyrrell, who read a short paper on "War Injuries of the Eye," gave an up-to-date example. A boy, eleven years of age, reputed to be "England's youngest air-raid warden," was admitted to hospital with a badly burned eye. His air-gun had become blocked by a pellet jamming in the rifle, and to free it he fired several others, which all stuck behind the first. Then he had the bright idea of heating the barrel in a watchman's coke fire, and, observing some melted lead run out of the muzzle, he put the muzzle to his eye to see if it was clear, whereupon a further stream of hot lead entered the eye. Mr. Tyrrell was able to pick out a complete cast of the conjunctival sac, and beneath it he found the cornea quite clear and bright, though the conjunctiva of the fornices was oedematous and parboiled. In the result there was nothing worse than a small symblepharon of the lower fornix. Burns of the cornea are very uncommon, and another speaker in the same discussion said that he, too, had seen a case in which molten metal had entered right into the eye and all that he had had to do was to take off a cast of the front of the cornea, leaving the cornea intact. It was suggested that the fluid in which the cornea was bathed was in a colloidal state and formed a protective layer which would not conduct heat, so that the cornea escaped undamaged.

Earlier Time for Receipt of Advertisements

Owing to the ever-increasing difficulties of production under war conditions it is now imperative that advertisements announcing vacancies for medical officers of health, hospital posts, locum-tenents, etc., should reach the Advertisement Manager, "B.M.J.", Tavistock Square, W.C.1, not later than first post on the Monday of the week of issue. If proofs are required the "copy" must reach this office on the Wednesday in the week preceding publication of the announcement.

The Medical Directory

The Editor of the *Medical Directory* (104, Gloucester Place, Portman Square, London, W.1) writes: To maintain the accuracy of our annual volume we rely upon the return of our schedule, which has been posted to each member of the medical profession. Should the schedule have been lost or mislaid we will gladly forward a duplicate upon request. The full names of the doctor should be sent for identification.

Corrigendum

In the article headed "Lactose for Prevention of Odour in the Closed-cast Treatment of Compound Fractures," by Drs. ALLAN D. WALLIS and MARGARET J. DILWORTH (May 17, p. 750) the first sentence of the third paragraph should read as follows: "In selecting a sugar for use in wounds lactose was chosen instead of glucose because, since its molecule is larger, *first*, a solution of it is isotonic with the blood contains more sugar, and, *second*, loss by absorption from the wound should be less."

PROBLEMS OF THE CIRCULATION *

BY

R. J. S. McDOWALL, M.D., D.Sc.

Professor of Physiology, King's College, University of London

Capacity of the Circulation

One of the greatest advances in regard to the circulation in the last twenty-five years has been the recognition of its variable capacity. It had long been recognized clinically that circulatory collapse might occur from the rapid removal of a large amount of fluid which had been compressing vessels in the chest or abdomen, or from excessive dilatation of the skin vessels by heat. It was recognized, too, that the cross-area of the open capillary bed, and therefore its capacity, was enormous; but not until the work of Dale and Richards (1918) and of Krogh (1918-19) was it realized that by far the greatest number of the capillaries in the body are not usually open, that they only dilate when local metabolic needs demand a greater supply of blood, and that a generalized opening leads to the capillaries' soaking up the blood like a sponge, with the result that circulatory failure occurs from a failure of the blood to return to the heart. This occurs when the capillaries dilate as a result of the action of toxins like histamine, or when there is loss of the nervous control of the blood vessels of a sufficiently large area.

The treatment of the condition when it occurred or was thought to have occurred clinically was obviously the supply of additional blood or blood substitutes to the circulation. The problem is not, however, quite so simple; for dilated capillaries are abnormally permeable—as we see typically in pleurisy with effusion—and allow the albuminous fluid of the blood to pass into the tissues in abnormal amounts. The use of blood has the advantage that its corpuscles convey the oxygen and assist in carbon dioxide removal, which is so vital for the prevention of generalized and fatal asphyxia; but the relatively low osmotic pressure of blood allows the passage of fluid through the dilated capillaries to continue. Various attempts have been made to supply more concentrated fluid. Gum-saline of a higher osmotic pressure than blood was eventually recommended (Erlanger and Gasser, 1919) as an improvement on the 6% solution originally advocated by Bayliss and made the subject of these lectures in 1918.

This problem was also made the subject of an Oliver-Sharpey lecture by Dale in 1923.

The availability of large numbers of blood donors has made possible the provision of concentrated or dried blood plasma or blood serum, which may be used in whatever concentrations are desired. These substances have the advantage that by their osmotic action they withdraw some of the fluid which has seeped through the capillary walls.

In actual practice these fluids are of special value in all varieties of haemorrhage in which there is not an increased capacity of the circulation but a diminution as a result of the constriction of vessels by the vasomotor centre, which compensates so far as possible for the loss of blood. When there is an increased capacity of the circulation there

is good evidence, as indicated in the next section, that the problem is by no means so simple as originally supposed, but it has been demonstrated, largely as a result of the work of Blalock (1931), that fortunately many cases of low blood pressure which were thought to be due to increased capacity of the circulation are in reality due to concealed haemorrhage.

The Peripheral Resistance

It has long been understood that without resistance to the outflow of blood from the arteries and elastic vessels a diastolic blood pressure would not be maintained. In these days of war we see the similar necessity for a nozzle on a fire hose if we are to obtain a constant jet of water during the time the pump is filling. Before 1918 it was taught in regard to the circulation that since the cross-area of the circulation was so large the peripheral resistance was located solely in the arterioles.

The recognition of the fact referred to in the previous section, that the majority of capillaries were normally not open but closed, led to other considerations, and Dale and Richards (1918) emphasized that a fall of peripheral resistance was in part responsible for the fall of arterial pressure due to histamine. It was amply confirmed by Hemingway and McDowall (1926) and by McWhan and McDowall (1937) that histamine caused a fall of peripheral resistance accompanied by increased venous outflow in limbs perfused with saline solutions.

This factor of the fall of peripheral resistance has been largely ignored in treating cases of low blood pressure because, as has been said, a generalized dilatation of blood vessels, whether produced as a result of loss of nervous activity by asphyxial products or by other toxins such as histamine acting directly on the capillaries, greatly reduces the return of the blood to the heart and masks the effects of the fall of peripheral resistance so far as venous return is concerned. The importance of this fall of resistance becomes apparent only when an attempt is made to bring about a recovery of the arterial blood pressure by the injection of blood or a blood substitute. Experimentally by a simple model, or by animal experiment, it is easy to demonstrate, since it is a simple fact of hydrostatics, that if the peripheral resistance is reduced it is not possible to cause a return of the arterial pressure to normal without at the same time producing a considerable rise in venous pressure. The most convincing experiment in relation to the problem is to study the effect of the injection of fluid into the circulation after section of the spinal cord high up. This section brings about a generalized dilatation of vessels, resulting in a fall of arterial and venous pressures. If an attempt is now made to return the blood pressure to normal by the injection of fluid the result is a complete failure, because there is not only an increased capacity but also a fall of peripheral resistance. In spite of a maximum output of the heart, enough fluid cannot be pumped out to maintain a high arterial pressure when the peripheral

* The second Oliver-Sharpey Lecture to the Royal College of Physicians of London, 1941.

resistance is so low. The example taken is an extreme case which rarely occurs, but it serves to indicate a point that has been commonly overlooked. It is as if we attempted to produce a jet from a hose without a nozzle by working the pump to the maximum of our ability. In the case of the circulation the venous pressure rises enormously, and this cannot be without importance, for it must be followed by all the sequelae which result from venous congestion. Further, the capillary pressure will be raised, and this will promote still further the seepage of fluid from the blood into the tissues—a fact which is especially important in relation to the lungs and pericardium.

How to restore the peripheral resistance once it has fallen becomes a subject of major importance, for often the patient dies in spite of all treatment. The difficulty is that we know of no drug which will constrict all the blood vessels in the body without impairing the heart. Drugs such as adrenaline, ephedrine, and pituitary extract merely drive the blood from the blood depots into the muscles, and their action is quite short-lived. Adrenaline and ephedrine exhaust the heart, and if continued may, as shown by Freeman (1933), of themselves bring about a fall of arterial pressure, it is thought, through causing asphyxia of the areas they shut down. Pituitary extract acts dangerously on the heart. Barium is too toxic. The preparation veritol (β (*p*-oxyphenyl-isopropylmethylamine) is probably the best, but its success has not been very great. It may be that a more suitable drug or combination of drugs will be discovered, but meantime it is as elusive as the philosopher's stone. One of the greatest difficulties in the problem is that in very few instances is any attempt made to diagnose accurately the cause of the fall of blood pressure which goes under the general name of shock, and until this is done as a routine there will be confusion between those cases in which there is a fall of peripheral resistance and those in which there is simple loss of circulating blood.

When possible we have to try to prevent the occurrence of the fall of arterial pressure, and a complete knowledge of how this may be brought about is of the utmost importance. I have already discussed this in a recent lecture given to the Royal College of Surgeons (McDowall, 1940).

The Problem of Fainting

Fainting, although quite a common phenomenon, offers a number of interesting problems. It occurs when the arterial pressure falls, and especially when it falls rapidly. There is no hard-and-fast line between the unconsciousness of fainting and that of shock, into which it may merge as in haemorrhage, but it is convenient to consider fainting as an evanescent phenomenon. Falls of blood pressure occur in cardiac impairment and from dilatation of vessels, separately or combined. A vessel dilatation which commonly produces an evanescent unconsciousness is the result of excessive external heat and toxins—notably that of influenza—which impair the vasomotor system. In the latter case the fall of arterial pressure through failure to adapt to the erect posture may be very considerable. The failure of the vasomotor system may be the result of fatigue of the system, as is seen in the fainting of soldiers on parade or lining the streets—especially on a hot day.

Since consciousness depends on the amount of oxygen supplied to the cerebrum, any state which impoverishes the oxygen-carrying power of the blood must increase the liability to fainting; of these, haemorrhage—notably menstruation—and anaemia are the most common. Muscular exercise, by opening up the vessels of the muscles, may in such persons produce fainting. A similar type of fainting may occur from sudden removal of pressure on vessels in the chest or abdomen. Interference with the pulmonary circulation also causes fainting. This may be the result

of the pooling of blood in the chest or of the excessive negative pressure of whooping-cough; it may also be caused by compression of the pulmonary vessels from excessive intrathoracic pressure produced by severe expiration with the glottis closed, as in straining at stool.

Fainting is not, however, confined to those who have any apparent circulatory deficiency, and may, as is well known, be produced psychologically—the psychologists would have us believe as a mental escape from environment from which physical escape is impossible. Lewis (1932) has described the phenomenon as a vasovagal syndrome because it is associated with a fall of blood pressure and slowing of the heart; it is presumed from an increase in the depressor reflexes. It would, however, be much better to look upon the condition essentially as a release phenomenon, the result of sympathetic paralysis or inhibition; for section of the sympathetic produces a similar result experimentally. One of our problems is whether the unconsciousness is in part the cause of the fall of pressure, for there is increasing evidence that sympathetic activity is much more related to the activity of the cerebral cortex than hitherto supposed. Since, however, unconsciousness produced in other and diverse ways does not necessarily result in such a marked fall of arterial pressure, it would seem that by some unknown means the psychological state affects sympathetic centres and that the unconsciousness is produced secondarily.

The well-known fact that the vessels of the skin are intensely constricted offers many problems. It is generally agreed that the fall of blood pressure is due to a dilatation of vessels somewhere, but evidence as to which vessels are dilated is somewhat circumstantial, and is assumed from the persistence of the fall of blood pressure after atropine has been given to prevent the cardiac slowing. The best direct evidence on the point is possibly that of John Hunter, who one day, when bleeding a patient, observed that the venous blood turned bright red just before the patient fainted. Since the skin vessels were presumably constricted we must conclude that there was a dilatation in the vessels of the muscles. The fact that the heart is slowed as a result of increased vagus action would also lead us, as suggested by Lewis, to conclude that the vascular component of the depressor reflexes, which, like the cardio-inhibitory reflex, is activated from the carotid sinus and cardio-aortic region, is also increased. This would bring about a generalized dilatation of vessels. If this explanation is correct it is difficult to understand why the skin vessels escape this general dilator reaction, for all experimental work goes to indicate that the skin vessels take part in the dilator reflexes from the aorta and carotid sinus. It may be that the vessels of the skin are differently controlled—perhaps they respond specially to a fall of internal pressure. Actually, as has been said, skin vessels respond to adrenaline differently from those of muscle, but the acute fall of blood pressure and the slowing of the heart preclude the possibility that adrenaline is concerned in the reaction. However it is produced, it must always be considered possible that the skin constriction is part of a hitherto undescribed defence reaction, of which immobility, simulating death, is a part. Such reactions are common among the lower animals.

High Blood Pressure

No consideration of the problems of the circulation would be complete without reference to high blood pressure, and its importance cannot be overestimated, especially at a time when too many public men are apt to be its victims. The subject has been set out by a very large number of writers for many years, and I shall not attempt to do more than give a survey of the problem as it now

appears to stand. Most valuable details on the subject have been published by Dawson (1925), who emphasized the mental factor; by de Wesselow (1934), who gave a most exhaustive review of the associated chemical changes; and by Pickering (1939), who has made extensive experimental studies of cases.

For the most part the problem now centres round the question of how the increased peripheral resistance is produced, but in regard to this there has unfortunately been a distinct tendency for those interested to take sides. Some suppose a neurogenic hypothesis, and others a chemical one in spite of the fact that admittedly the high blood pressure may be produced from a variety of causes and may be but a common symptom. Further, the two hypotheses are not so mutually incompatible as at first sight appears.

There are certain incontrovertible facts which seem to be, but may not be, relevant. High blood pressure occurs in the following conditions: mental stress, severe exercise, adrenal tumours, nephritis, gout, eclampsia, chronic lead or alcohol poisoning. Experimentally, temporary rises may be produced by stimulation of sensory nerves, of the sympathetic direct or through the vasomotor centres, by oxygen want or accumulation of carbon dioxide, and by the injection of extracts of the adrenal, the pituitary, the cortex of the kidney known as renin (Pickering and Prinzmetal, 1937; Tigerstedt and Bergman, 1898), and of certain pressor amines (Barger, 1914). It may also occur in suitably rested animals as an overcompensation to the injection of depressor substances such as histamine (McDowall). A persistent rise of pressure may also be produced experimentally by partial occlusion of the renal arteries (Goldblatt, Lynch, Hanzal, and Summerville, 1934). This fact, together with the occurrence of high blood pressure in nephritis and the presence of a pressor substance (renin) in the kidney, has caused an undoubted and justifiable bias of opinion towards the view that the kidney is somehow concerned: but, in spite of most painstaking endeavour, conclusive evidence regarding the exact factor concerned is lacking. No pressor substance has been demonstrated in the blood of patients suffering from any variety of high blood pressure. It cannot be dialysed out, nor has the injection of large quantities of blood from patients into normals any effect (Pickering, 1935-6; Prinzmetal, Friedman, and Rosenthal, 1936). That, however, is not to say that no pressor substance is present, but merely that the means of testing for it are inadequate. It may be that the pressor substance is present only in very small amounts but that its effects are cumulative on the arterial wall. It should, however, be pointed out that no substance having such an action has yet been discovered. Further, it is possible to inject into animals a dose of adrenaline or pituitary which will constrict the skin very considerably yet be insufficient to raise the blood pressure. The blood pressure is really too crude a criterion of the existence of small doses of a pressor substance. It is also possible that normal subjects are more capable of destroying the chemical substance than those with hypertension, and therefore it is not possible to demonstrate the action of the pressor substance on the normal circulation. It is possible to carry this idea still further and to reverse the usual chemical conception of hypertension and suggest that the primary fault is failure to destroy a pressor substance which may exist normally in the blood or be liberated as a result of some pathological process. The view, however, has considerable experimental support, for the blood of hypertensive dogs has been found to be more pressor if the kidneys of a recipient dog are removed, and may explain why it is that removal of one kidney in man may occasionally result in a rise of blood pressure, and why the blood of hypertensive patients may have no effect on normals. Already, too, there is evidence

that extracts of normal kidney may be of benefit in certain cases of high blood pressure (Grollman *et al.*, 1940; Pa *et al.*, 1941). There can be little doubt that the study of experimental hypertension produced by compression of arteries is of very special importance. It indicates, for example, that it is possible to produce a persistent high blood pressure of renal origin although there is no evidence of renal disability from a study of the urine. The differentiation between so-called essential hypertension and that chronic nephritis may therefore be quite artificial and of a matter of degree of kidney damage.

The Nervous Hypothesis of Hypertension

Those who support the nervous hypothesis have likewise or even more so, failed to produce conclusive evidence. There seems to be little doubt that hypertension in man is a disease of civilization. It is stated to be absent among lazy African natives, and affects in a remarkable degree some of the most active persons of our time, but statistically accurate data on this subject are difficult to obtain. In certain families there is a tendency to the condition has been noted by many observers. Dawson, however, suggests that the high blood pressure is not produced by striving, but that an existing tendency or trait is made manifest by striving. It is easy to imagine that sustained mental strain would bring about constriction of the peripheral vessels and many anxious patients appear to be in such a state. Such stress is, however, accompanied by cardiac acceleration. Some observers have found that as a rule the blood pressure is appreciably less in patients examined at home than in the same patients examined in the clinic, and there can be no doubt that blood-pressure readings are of little value unless the patient is in a state of mental quiet and quite familiar with the application of the sphygmomanometer armlet, etc. The effect of mental factors appears to be indicated by the fact that in some patients, a large dose of a sedative may reduce the pressure and in some there is an increased metabolic rate. This would suggest that a general increase in sympathetic activity occurs, and in this connexion it is of some interest to note that very high blood pressures are common in male cats during the spring sexual season—when the sympathetic is very active (Arnage, McDowall, and Mathur, 1932). On the other hand there is no evidence of a general increase of sympathetic activity which would produce a rapid heart rate, a dilated pupil, or sweating.

We have therefore to ask ourselves, Can mental strain produce more remote effects on the circulation? There are several possibilities. That which since the time of Savile has received most attention is the possibility that frequent use of the arterial muscle may lead to its hypertrophy and that as a result the lumen becomes narrowed. Several workers have attempted to repeat the observation of Savile—that the muscle of the media of the arterial wall was hypertrophied—with varying results. The difficulty is that of deciding when hypertrophy of arteries of different sites is present. The possibility that hypertrophy actually interferes with function has also been considered by some, but is difficult to imagine; but such a state has been shown to exist in the hearts of racing greyhounds, in which cardiac hypertrophy inside a relatively fixed pericardium may lead to cardiac impairment, which is relieved by slitting of the pericardial sac (O'Shaughnessy).

Pickering (1935) and Prinzmetal and Wilson (1936) claim to have negated the nervous hypothesis by finding that hypertensive subjects showed no greater increase than normals of the blood flow through the hand when its vasomotor control was removed by raising the body temperature. How far this conclusion is valid is, however, a little uncertain. It excludes certainly any of the immediate

effects of increased sympathetic action, which, as has been said, are already probably eliminated by the absence of a fast heart, but it does not exclude the possibility of hypertrophied arteries, which could still dilate to loss of vasomotor control or to suitable chemical stimuli. In regard to this latter point it ought to be mentioned that a fall of arterial pressure does not necessarily mean that the vessels concerned in a high blood pressure have dilated. Histamine or amyl nitrite, for example, may lower the blood pressure in hypertensive patients by dilating the capillaries and producing capacity effects; indeed, histamine is known to lower arterial pressure while actively constricting arteries. The finding that certain vasodilator drugs lower the blood pressure in cases of hypertension is of no significance in relation to the problem.

It should be pointed out that Oliver (1896), who gave extensive study to the problem, was quite familiar with the fact that the radial artery in patients with high blood pressure caused by chronic nephritis reacted quite normally to changes in posture. It was more constricted when the subject was standing than when recumbent. He, with his arteriometer, examined a number of persons who suffered from periodic attacks of high blood pressure, and found that in these the postural variations in radial calibre disappeared, although between the attacks they were quite normal. He considered, however, that the size of the lumen of the radial artery usually depended on the blood pressure, but pointed out that in all cases of hypertension the lumen of the artery diminished in size progressively.

Another possibility is that the kidney is particularly affected by mental stress; but while there is such confusion regarding the function of nerves on the kidney it is difficult to go further than to mention it. It is possible, too, that the mental stress, by interfering with digestion, which it does admittedly, or with the metabolism, may lead to toxic changes.

Thus it becomes evident that the nervous and chemical hypotheses may yet be brought together; and, in any case, it is not sufficient to say that the kidney or any other organ is at fault without at the same time considering why it is at fault.

Conclusion

In closing these lectures I cannot but plead for the closer relation between physiology and medicine which these lectures were designed to promote. I trust the necessity for this has been evident from what I have said. More will agree that it is needed than did in Oliver's time, but too often the statement is but a pious expression of opinion to which no effect is given. There are still too many who are satisfied with the diagnosis and treatment of disease according to recognized formulae and who are not interested in the progress of their subject. Would that the spirit which imbued Oliver were more prevalent; but may we hope that those who plan the medicine of the future will have vision beyond the immediate needs of the patients, and will organize so that medical research will be as much a routine as is treatment.

THE INCIDENCE OF DYSPEPSIA IN A MILITARY HOSPITAL

BY

JAMES H. HUTCHISON, M.D., M.R.C.P., F.R.F.P.S.

Major, R.A.M.C.

The occurrence of dyspepsia in the Army during the present war has proved to be one of the major medical problems. Several investigations have been recorded in which the incidence of the various causes of dyspepsia has varied considerably. Payne and Newman (1940) reported that 60% of 287 patients, many of whom were evacuated to England from the B.E.F., had duodenal ulcer. This finding has been criticized by Hartfall (1941) and Spillane (1941) as not being consistent with their experience among soldiers serving in this country. Two factors may explain this discrepancy: Payne and Newman's cases included many from the B.E.F. which had been carefully selected by C.C.S.s and base hospitals in France as likely to be instances of organic disease; and there can be little doubt that in the early days of the war many men who had been suffering from peptic ulcer for some years in civil life were mobilized—for example, reservists and volunteers with special training allowing of their rapid dispatch to France. Presumably most of these men have now been discharged from the Army by medical boards, and it might be expected that the incidence of organic dyspepsia among troops would consequently be lower than in the early months, especially as civilian medical boards examining recruits are more aware that ulcer cases do not do well under military conditions.

Saffley (1941) reports that of 320 soldiers investigated radiologically 50.3% were "normal" and 38.7% had peptic ulcers. He also states that of 338 cases of dyspepsia in a near-by military hospital from which he drew his patients no lesion was found in 124, ulcers were present in 133, and the remarkably high proportion of 38 cases were diagnosed as anxiety neurosis. Working in another military hospital, I have not found this high incidence of neurosis, and the psychiatrist there has informed me that few cases of neurosis passed on to him have symptoms referred to the gastro-intestinal organs. On the other hand, the occurrence of peptic ulcer among all cases of dyspepsia referred to this hospital has been considerably less than that found by Payne and Newman (1940) in cases evacuated from the B.E.F. It was therefore deemed worth while to publish the incidence of the various types of dyspepsia investigated by us during a period of four months—November, 1940, to February, 1941—especially as these were cases sent "direct" from units in the area.

Method of Approach

In the vast majority of instances the question to be answered was, Is there or is there not an active ulcer present? A summary will therefore be given of our method of approaching a possible case of ulcer dyspepsia, and of the basis on which the diagnosis was made. This will be followed by a detailed account of all types of cases and by a discussion of further points in differential diagnosis.

Most of the cases of dyspepsia referred to this hospital were first seen at the out-patient clinic, where the history was taken and a careful clinical examination was made. With few exceptions investigation by fractional test meal (F.T.M.) was then carried out in the out-patient department by appointment, unless it was at once obvious that

the condition was not ulcer dyspepsia, or if documentary evidence was forthcoming that the soldier had been adequately investigated elsewhere within the preceding three months. If the history, clinical findings, and result of the F.T.M. were suggestive of ulcer the case was put on the waiting list and hospital investigation arranged within a week or two, either here or in a neighbouring civil or E.M.S. hospital. Some patients—e.g., those with bleeding ulcers, men over 40 years with a short history, and men who appeared ill and in pain—were admitted direct from the out-patient clinic. If the history was not suggestive of any of the recognized organic causes of dyspepsia and if clinical examination and the F.T.M. failed to reveal evidence of organic dyspepsia the patient was returned to the unit with a note to the medical officer recommending any simple measures that seemed appropriate. Further investigation was rarely thought necessary, and often was undesirable, in such cases, as the soldier is notoriously highly suggestible and the idea of disease is more easily implanted than eradicated. In special circumstances a diagnosis of peptic ulcer was made in the out-patient clinic without in-patient investigation. Thus if a man had a paramedian abdominal scar with a typical history of ulcer dyspepsia and a history of perforation, gastro-enterostomy, etc., and if the F.T.M. done here showed a climbing hyperchlorhydria, there was considered to be enough evidence to justify "boarding" him as a case of peptic ulcer. Or if a man gave a typical history of ulcer along with a convincing story of having been investigated in civil life and treated by Sippy or Lenz type of diet, then a climbing or plateau hyperchlorhydria with consistent clinical signs—e.g., localized epigastric tenderness, pallor, and often loss of weight—was regarded as sufficient evidence of the existence of an ulcer. Marked hyperchlorhydria—i.e., a curve which after the first hour was consistently at or above 60 c.cm. N/10 HCl—was required before such a step was taken. Such cases were labelled peptic ulcer, as it was often impossible to determine the location of the ulcer accurately without another barium meal and as the aim was primarily to determine whether or not a man was fit for military duties. The in-patients were investigated by a second F.T.M., a barium meal, and often examination of faeces for occult blood; and the diagnosis was based on a careful consideration of the history, a clinical examination, and the results of special investigations. Ulcer was never diagnosed if the radiologist reported a normal stomach and duodenum. On the other hand, a marked hyperchlorhydria in the presence of active symptoms and consistent clinical findings, if there was persistent deformity and defective filling of the duodenal cap, was taken to be enough evidence of duodenal ulcer: it was thought to be wrong to base a diagnosis on "direct" vision of an ulcer crater only and on no other grounds. In some cases reflex duodenal spasm was excluded by cholecystography, pyelography, etc., if the history or clinical examination suggested such a possibility. The presence of occult blood in the faeces was sometimes helpful. Gastric ulcer was, of course, diagnosed only in the presence of "direct" radiological evidence.

During the period November, 1940, to February, 1941, 257 cases presenting symptoms of dyspepsia as a principal feature were seen at this hospital. Of these, 45 must be disregarded, as a final diagnosis was not made here, some having moved to another area before investigation could be started, some having been admitted to near-by civil or E.M.S. hospitals from our waiting list by arrangement, and a few recent ones having to await admission. The remaining 212 cases were fully dealt with and investigated by us; 88 were in-patients and 124 out-patients. These two groups are discussed separately.

In-patients

In Table I the in-patient cases are classified according to type of dyspepsia; it gives the numbers and percentage incidence of each type, the average age of onset according

TABLE I.—In-patients

Diagnosis	No.	Percentage	Average Age of Onset	Onset in Civil Life	Onset in Army
Duodenal ulcer	30	34.1	27.5	25	5
Gastric ulcer	10	11.4	29.5	9	1
Functional dyspepsia ..	25	28.4	27.2	9	16
Acute gastritis	4	4.6	39.0	0	4
Chronic gastritis	2	2.3	33.5	2	0
Psychoneurosis	5	5.7	18.4	5	0
Hyperchlorhydria	3	3.5	17.0	2	0
Achlorhydria	1	1.1	39.0	0	1
Dyspepsia (aetiology obscure)	2	2.3	40.0	1	1
Constipation	1	1.1	33.5	0	1
Carcinoma of stomach ..	1	1.1	50.0	0	1
Appendicular dyspepsia ..	1	1.1	27.0	1	0
Chronic cholecystitis	1	1.1	34.0	0	1
Pulmonary tuberculosis ..	1	1.1	42.0	0	1
Banti's syndrome	1	1.1	19.0	0	1
Total	88	100		51	37

to the patient's history (which is not always as reliable in the Army as in civil life), and the numbers of each type originating during Army service or in civil life.

45.5% of the 88 cases were proved to be ulcers, the incidence of gastric ulcer being remarkably high, although 5 of these were at the pylorus and were judged by the radiologist to be gastric and not duodenal. 28.4% were labelled functional dyspepsia. This group was composed of men complaining of active indigestion, nearly always of a type similar to that found in ulcer cases; but in the majority the history was atypical in some direction, and investigation by the F.T.M., barium meal, and occult blood test, and often cholecystography, chest radiography, urine culture, etc., was negative, although transient hyperchlorhydria or mild hypochlorhydria was found in some or there was radiological evidence of hypermotility or atony. In no instance was this diagnosis made if any well defined sustained abnormality was reported. A point of clinical interest is that in the functional dyspepsia group abdominal tenderness was rare, whereas in the ulcer group well-defined localized epigastric tenderness was usually present. In the 4 cases of acute gastritis there was vomiting with or without diarrhoea; some were febrile others dietary in origin. The 2 cases of chronic gastritis had hypochlorhydria, with excess mucus in all specimens and a compatible history; the barium meal served to exclude other causes. Of the 5 labelled psychoneurosis 3 were cases of hysterical vomiting, 1 was globus hystericus and 1 was aerophagy that was manifestly hysterical investigation by barium meal was negative in every case. In all 5 cases the hysterical symptoms had been present several years before enlistment. Of the 2 cases of hyperchlorhydria 1 had a very high climbing curve and an atypical history, and two barium meals failed to reveal an ulcer of stomach or duodenum. This patient responded well to treatment with alkali and light diet, and returned to duty. The other also showed a climbing curve, but with a history typical of duodenal ulcer, although the barium examination failed to reveal any abnormality: as there was a fifteen-year history and the symptoms did not improve on alkali and simple dietary measures, and as he was physically under-developed, he was "boarded" out of the Army. The case of achlorhydria, confirmed by histamine occurred in a thin middle-aged man who complained of anorexia and loss of weight, and in whom all other investigations were negative. He returned to duty, having gained weight after treatment with acid, hydrochlor. dil. on a graded diet. Two cases were labelled dyspepsia of unknown type. One of these was that of a man aged 5 who had an eight-year history of recurrent attacks of

vomiting, each lasting two to three weeks: he was admitted during an attack. Clinical and barium examinations were negative, and the F.T.M. showed only mild hyperchlorhydria and no mucus. Renal and chest investigations were also negative. As he was of low mentality and had pronounced arteriosclerosis he was "boarded" out of the Army. The other case of dyspepsia of unknown type was that of a man aged 33, with epigastric pain after meals not relieved by alkali or food, in whom a barium meal showed exaggerated gastric mucous folds and spastic duodenal cap without obvious cause. As he was unable to swallow a Ryle tube and gastroscopy could not be performed the diagnosis remained uncertain (? chronic hypertrophic gastritis). Simple treatment allowed of his return to duty. Among the remaining cases the patient with appendicular dyspepsia had a recurrent subacute appendicitis, and the case of pulmonary tuberculosis occurred in a prematurely-old man aged 43 whose only symptoms were gastric in origin and in whom fibroid tuberculosis was detected only after gastric tests were negative. In this series of 88 cases there were 3 of haematemesis and melaena—2 due to duodenal ulcer, which recovered, and 1 in which death occurred after repeated severe haematemeses and in which necropsy showed advanced changes of Banti's syndrome. Only 1 of the 88 patients was admitted with perforated (pyloric) ulcer.

Out-patients

In Table II the out-patient cases are classified in a similar manner. Of the 124 cases 35.5% were diagnosed as peptic ulcer on the basis already outlined. As might be expected

TABLE II.—*Out-patients*

Diagnosis	No.	Percentage	Average Age of Onset	Onset in Civil Life	Onset in Army
Peptic ulcer ..	44	35.5	yrs. 26.9	36	8
Functional dyspepsia ..	54	43.6	25.0	26	28
Acute gastritis ..	2	1.6	27.0	0	2
Chronic gastritis ..	4	3.2	38.0	2	2
Psychoneurosis ..	6	4.8	20.3	4	2
Hyperchlorhydria ..	2	1.6	25.0	2	0
Achlorhydria ..	3	2.4	31.0	2	1
Appendicular dyspepsia ..	4	3.2	29.5	0	4
Chronic cholecystitis ..	1	0.9	37.0	1	0
Malingering ..	4	3.2	29.0	0	4
Total ..	124	100		73	51

the functional dyspepsia group (43.6%) is greater than in the in-patient series; these cases gave an atypical history, although often there were points of similarity with ulcer dyspepsia cases, in which the patient looked fit and in which epigastric tenderness was absent. In no instance did the F.T.M. show any sustained departure from normal, although mild degrees of transient hyperchlorhydria and hypochlorhydria, as well as a suggestion of hypertonia or hypotonia, were not uncommon.

Six cases are included under the heading psychoneurosis: 2 were cases of neurotic aerophagy (1 of long duration, 1 dating from enlistment); 1 was a case of hysterical dysphagia with other hysterical stigmata: 1 was that of a man, with visceroptosis as shown by barium series, who had already been discharged from the Army in peacetime for this complaint and was markedly neurotic; the remaining 2 were cases of anxiety neurosis following bombing and melancholia, in neither of which were dyspeptic symptoms outstanding, but which were referred on this account.

The cases of hyperchlorhydria showed fairly high curves; 1 had a quite atypical history, and the other had had a barium test meal in another military hospital just previously. The 3 cases of achlorhydria were in comparatively young men who had normal blood counts and minor symptoms. Of the remaining patients 4 were

regarded as malingering: 2 of these were under escort, 1 had already been investigated in another military hospital, and, like the fourth man, in whom investigation was not regarded as necessary, the bizarre history was impossible of belief. In all cases the men's attitude was obviously that of trying to "put one over" on the M.O. These men were warned of the possible consequences of untrue complaints. While I cannot agree with the view held by some that malingering does not occur in the modern Army, it is in my experience extremely uncommon.

Discussion

This analysis will not elicit any facts in the aetiology of peptic ulcer. However, several interesting points emerge therefrom. First, the incidence of ulcer in this series is probably very similar to that found in civil hospital practice. This finding is not incompatible with the figures of Payne and Newman (1940), for reasons already mentioned. My experience with the B.E.F. was that a much higher incidence of ulcer was found than in the present series, although in the evacuation from France the actual figures were lost. It will be seen from the tables that 67 ulcers began in civil life, against 17 during Army service. Of the latter, 3 were in Regular soldiers and 4 in Regular officers of many years' service; therefore only 10 out of the 84 cases of ulcer arose in the Army during this war. The majority of ulcer cases in this series occurred in reservists during their period in civil life and in volunteers and conscripts from 27 years upwards. These figures do show that the problem of peptic ulcer incidence in the Army does not differ from that in civil life, and it is probable that the increased incidence of ulcer among civilians since the last war is the major factor in the prominence of such cases in this war in comparison with the Army of 1914-18. Increased awareness of its existence is probably also a factor in a medical service which, so far, has been less busy with battle casualties than in the previous war, so that more time can be given to cases of dyspepsia. The disposal of the man with peptic ulcer has been by medical board and discharge from the Army, as it is clear that this kind of man does not do well in the Army. The only exceptions to this rule have been those highly trained Regular officers who were given a full course of medical treatment: the officer can usually regulate his diet in a way that the rank and file cannot, and the officers in this series so treated have returned to duty symptom-free.

The incidence of 79 cases of functional dyspepsia in 212 cases is probably higher than that met with in civil life, and it will be seen that 44 of these had their origin during Army service, as against 35 arising in civil life, a finding that is not unexpected. I have no doubt that in each of these cases the man was suffering from genuine dyspepsia due to some, often minor, disturbance of function: the word "functional" is used advisedly to indicate this, and not loosely to include all cases in which organic disease could not be found. The aetiological basis of this type of case is not easy to define, although it is probably no more obscure than the aetiology of peptic ulceration. As already mentioned, evidence of some functional disturbance was frequently present, such as minor degrees of hyperchlorhydria, hypochlorhydria, hypermotility, gastroptosis, or atony, although sometimes it was not of a degree consistent with the severity of the symptoms. In a number of cases dental sepsis was present. It is obvious that the causes of this type of dyspepsia lie deeper than in the factors which have already been mentioned and which were often absent. In some cases the sudden change from civil diet to Army diet and from a sedentary life to vigorous training undoubtedly served at least to aggravate any tendency to gastric upset. In my opinion a potent factor in those

cases was worry and anxiety, often arising from circumstances—domestic, financial, etc.—already present in civil life and carried with the man into the Army. In other cases the source of worry was associated with the war, although not with Army routine. It is not always realized that the soldier in this war has the same sources of worry as are so universal among the civilian population: thus very many men are anxious about their wives and parents in bombed areas, or about their families evacuated to unfamiliar surroundings. Then there are men who have left good civilian positions for much less remunerative Army service, not all having their pay made up; others have had their training for a skilled but non-essential occupation interrupted and are apprehensive of the future. Army life itself gives few causes of worry, as the soldier is well looked after; but undoubtedly some men worry about the uncertainty of when their next move will be made and where it may take them. It seems reasonable to suggest that anxiety may play a part in the production of dyspepsia in men whose autonomic nervous system is constitutionally somewhat precariously balanced, especially as it is agreed that worry has an adverse influence on the symptoms of established peptic ulcer. In pointing out the factor of anxiety it is not suggested that those men suffered from anxiety neurosis: quite the contrary, as with them, unlike cases of anxiety neurosis, there was adequate cause for worry. Nor was the anxiety of pathological intensity or such as to interfere with their general efficiency: such men were never medically "boarded," and simple measures were sufficient to fit them for duty. They were firmly assured that they did not suffer from any organic disease and that their health was good and would improve under Army conditions. In only a few cases were medicines—e.g., acid, hydrochlor. dil. or magn. trisilicat.—necessary. Details of the findings were always sent to the unit M.O.

The incidence of actual neurosis was very low; 9 of the 11 cases arose in civil life and were unchanged by Army service, save possibly for the better. The incidence of chronic cholecystitis and gastric carcinoma is much lower than in a civil hospital, probably owing to the lower average age of our patients.

Conclusion

This analysis shows that the problem of dyspepsia in the Army is more or less the same as that of peacetime civil life, any differences being determined by such factors as age groups, sex, general anxiety about the war, etc. Army conditions have not produced any new syndrome, and it is very probable that they have not increased the incidence of gastric or duodenal ulcer. The increased incidence of dyspepsia in the Army of this war finds its parallel in a comparable increase in the civil population since the last war, and is directly related thereto.

Summary

257 cases presenting symptoms of dyspepsia were seen at a military hospital during a period of four months. Of these, 212 are considered in detail.

The incidence of peptic ulcer was similar to that found in civil hospitals.

There is an increased incidence of functional dyspepsia, the aetiology of which is discussed.

The analysis does not reveal that Army conditions have any marked effect on the production of dyspepsia.

Thanks are due to Colonel R. G. Gordon, A.M.S., officer commanding, for permission to publish this paper, and for his encouragement during its preparation.

GASTRO-PAPILLOMATOSIS DUE TO VITAMIN A DEFICIENCY INDUCED BY HEATED FATS*

BY

STEPHAN BECK, M.D.†

AND

P. R. PEACOCK, M.B., B.S., M.R.C.S.

(From the Research Department of the Glasgow Royal Cancer Hospital)

Since Fibiger (1913) first described experimentally induced tumours of the fore-stomach of the rat many other workers have investigated this problem without, however, reaching a satisfactory explanation of his original results. Fibiger described three types of lesions: (a) multiple papillomata of the fore-stomach; (b) squamous carcinoma of the fore-stomach; and (c) carcinoma of the tongue. He also obtained a carcinoma in a mouse that was transplantable. These lesions he attributed to the presence of a nematode, *Gongylonema neoplasticum*, derived from cockroaches which were present in the animal-house and which were consumed by the rats in addition to their diet of white bread and water. Passey (1934) drew attention to the fact that such diet must have been deficient in vitamins, and that vitamin A deficiency in the absence of the gongylonema can lead to papillomatosis of the fore-stomach of the rat. Cramer (1937) reviewed experimental work, including his own investigations bearing on Fibiger's results, and concluded that "diet and parasite are in themselves not sufficient to account for the lesions observed by Fibiger, and that there must be yet another factor involved which has not yet been identified." More recently Roffo (1938, 1939) claimed to have obtained a wide range of pathological lesions, including ulcers, papilloma, and carcinoma of the fore-stomach, adenocarcinoma of the glandular stomach, and sarcoma of the stomach and liver, in rats fed with heated or ultra-violet-irradiated cholesterol, and with overheated animal and vegetable fats. It is clear from the copious illustrations in his papers that Roffo has induced marked hyperplasia of the epithelium of both parts of the rat's stomach, amounting in some cases to histological evidence of malignancy, though the carcinomata do not seem to have metastasized to the liver, as might have been expected. The sarcomata, however, metastasized freely. These experiments are therefore of outstanding interest and demand independent investigation. Roffo believes that carcinogenic hydrocarbons are formed from sterols by the action of heat or ultra-violet rays, but, according to Cook and Kennaway (1940), his views on the nature of the chemical changes involved are inadequately supported by his experimental evidence. The presence of carcinogenic hydrocarbons in the food has been shown by Waterman (1939) to be capable of inducing tumours in the fore-stomach of mice.

In this laboratory an examination of a variety of fats has been made, after different conditions of heating, for the possible presence of known carcinogenic hydrocarbons, but nothing having the characteristic fluorescent spectrum of these substances has yet been demonstrated. It seems possible, therefore, that other types of carcinogen may be partly responsible for Roffo's experimental results. The suggestion that ordinary cooking fats may develop carcinogenic properties under the action of heat raises a practical problem which might have a bearing on the incidence of gastric cancer in man. The fats used in Roffo's experiments were apparently heated to 300–400° C., a higher

* Communicated to the Pathological Society of Great Britain and Ireland at Glasgow on July 4, 1941.

† Working under a full-time grant from the British Empire Cancer Campaign.

range of temperature than is ordinarily reached in domestic cooking, but it seemed possible that similar changes might occur progressively in fats repeatedly heated at lower temperatures. Even in times of peace economic conditions habitually forced a large part of the community to use fats repeatedly for cooking, and our experiments were therefore designed to imitate the worst conditions of frying likely to be in daily use, and to test the fats so treated by feeding them to rats and mice.

Experimental

1. A mixed cooking fat (equal parts of cotton-seed oil and whale oil) was heated to 200-220° C. in a closed iron saucepan for twenty to thirty minutes on thirty consecutive weekdays. The total time of heating amounted to about twelve hours. White bread was fried each day in this fat, allowed to cool, and then fed to 50 Norwegian hooded rats, maintained on a basal diet of whole oats, green vegetables, and water, with the addition of about 2 c.cm. of milk per rat three times a week and 2 grammes of carrot once a week after the first two months. When this experiment had been in progress for twelve months 40 rats had died, of which 8 showed multiple papillomata—6 with central ulceration—1 had a single unulcerated papilloma, and 2 showed irregular hyperplasia of the epithelium, all the lesions occurring in the fore-stomach. One rat developed a carcinoma of the lower lip. As in the foregoing experiment the bread was heated as well as the fat, this variable factor was eliminated in subsequent work by heating the fats alone and, after cooling, spreading them on white bread for feeding to the animals, using unheated fat spread in similar amounts as a control. The survivors of this first group of rats were fed in this manner for a further period of seventeen months, with the addition of about 2 grammes of carrot per rat four times a week, for reasons given below.

2. Twenty-four inbred Wistar albino rats were fed on the basal diet, with the addition of pure lard heated on thirty consecutive weekdays to 200-220° C. for twenty to thirty minutes.

3. Twenty-four Wistar rats were fed on the same basal diet, with the addition of cotton-seed oil, heated in the same way.

4. Twelve Wistar rats were fed on the basal diet, with the addition of unheated lard.

5. Twelve Wistar rats were fed on the basal diet, with the addition of unheated cotton-seed oil. (In Groups 2 to 5, after two months, 2 grammes of carrot once a week, and after a further five months four times a week, was added to the diet.)

6. Fifty stock mice were fed on the basal diet, with the addition of repeatedly heated mixed cooking fat spread on white bread, as described in the second paragraph under Group 1. (After two months 0.5 gramme of carrot once a week, and after a further ten months six times a week, was added to the diet.)

Litters of rats were divided between Groups 2 to 5 so that the groups were genetically comparable. During the first year of these experiments symptoms suggestive of avitaminosis-A were observed in young rats, particularly in Groups 2 and 3. The difference between these groups and the controls became more marked as time passed. The animals were smaller and less robust than the controls, had dry fur and slight xerophthalmia, and avoided exercise except in pursuit of food. As the control animals showed no such symptoms it seemed that the addition of heated fat had in some way neutralized or interfered with the metabolism of the dietary vitamin A. This possibility was tested in the following manner:

7. Twenty-four Norwegian hooded rats were fed on the basal diet, with the addition of about 3 c.cm. of milk and about 2 grammes of carrot once a week. This diet cannot be considered deficient in vitamin A. After four days the following additions to the diet were made: (a) 6 rats received 0.5 gramme of unheated lard six days a week; (b) 6 rats received 0.5 gramme of lard heated at 327° C. for one hour six days a week; (c) 6 rats were similarly fed with lard heated at 220° C. for twelve hours; and (d) 6 rats were similarly fed with lard heated at 220° C. for one hour. After two months 2 rats from each group were killed and their livers rapidly removed, rinsed in physiological saline,

minced, and desiccated. One gramme of desiccated liver was shaken with 5 c.cm. of chloroform for five minutes, the extract was then decanted, and dilutions of 1/1, 1/2, 1/4, up to 1/128, with chloroform, were made in a series of test-tubes. To each tube, containing 0.5 c.cm. of extract, 2 c.cm. of 30% solution of antimony trichloride in chloroform was added, and the highest dilution in which the blue vitamin A colour reaction could be detected was noted. The results of these estimations are shown in Table I.

TABLE I.—Relative Vitamin A Contents of Rat Livers

Rat No.	Lard	Vitamin A Content of Liver (Control = 1)
375B 376B	Unheated (control)	1 1
372B 373B	Heated, 220° C. 1 hr.	1 1
363B 366B	Heated, 220° C. 12 hrs.	1/2 1/2
361B 362B	Heated, 327° C. 1 hr.	1/4 1/8

It will be seen that the vitamin A content of the liver was reduced in proportion to the degree and duration of heating to which the lard was subjected. The remaining rats in this experiment were then fed for one month on a diet rich in vitamin A (basal diet, plus 2 grammes of carrot daily); one from each group was sacrificed, and the liver vitamin A estimated in the above manner. No differences were found between them, showing that the interference with vitamin A metabolism due to the heated lard was not permanent. The remainder of the animals are still under observation.

When animals died their stomachs were washed out and then filled with 10% formal-saline and left to fix for twenty-four hours before being opened. Fixation in this way gave very satisfactory preparations, free from distortion. All the stomachs were subjected to independent histological examination by Dr. L. Woodhouse Price, who reported his findings without knowing the details of the experiment. This is the routine procedure with all histological material in this laboratory. All but three lesions classed as papilloma were histologically confirmed. The results are shown in Tables II to V.

TABLE IV.—Gastric Lesions in 3 out of 14 Wistar Rats, surviving for More than 4 Months, fed on Basal Diet plus repeatedly Heated Cotton-seed Oil (11 Died without Lesions)

Rat No.	Duration of Experiment at Death	Lesions
878	117 days	1 ulcerated papilloma of fore-stomach
969	196 "	" "
715	318 "	" "

TABLE V.—Gastric Lesions in 3 out of 45 Stock Mice surviving for more than 4 Months, fed on Basal Diet plus repeatedly Heated Cooking Fat (41 Died without Lesions; 1 Survives)

Mouse No.	Duration of Experiment at Death	Lesions
1104	271 days	1 papilloma of fore-stomach
1106	279 "	" "
1134	355 "	Diffuse hyperkeratosis of fore-stomach

In the three groups of rats receiving repeatedly heated fats in addition to the original basal diet 77 survived for more than four months, and 17 of these died within the first year of the experiment and had papillomata in the fore-stomach. Control rats (receiving unheated fats) dying within the same period showed no papillomata, but 2 had minor degrees of hyperplasia. Among 25 old rats (over 2 years) from other experiments 3 showed hyperkeratosis of the fore-stomach, 1 diffuse hyperplasia, and 1 a simple papilloma of the fore-stomach. In our experience similar lesions have not been observed in control rats under 2 years old.

The benzidine test was carried out on stomach contents in cases showing brownish discoloration of the glandular stomach, and was found to be positive, confirming the presence of blood in the stomach cavity, probably derived from small ulcers. Papillomata, ulceration, and consequent haemorrhage appear to be definitely related to the feeding of repeatedly heated fat and associated with symptoms of varying degrees of avitaminosis-A. To test the possible interrelation between these pathological states 10 rats that had been under experiments for a year and 31 for seven months were given a diet rich in vitamin A, consisting of rat-cake nuts (see accompanying formula) daily, carrot 2 grammes four times a week, and about 2 c.cm. of milk once a week, while continuing to receive the differently treated fats as before. Six of these rats died after being on the vitamin-A-rich diet for more than a year, and none of these showed any gross lesion of the stomach. Two survivors are still under observation. The others are accounted for in the tables.

Rat-cake Formula (Supplied by the North-Eastern Agricultural Co-operative Society, Ltd., Bannermill Place, Aberdeen)

Wheat offal (fine middlings No. 2)	19.2%
Ground wheat	19.2%
Sussex ground oats	19.2%
Ground barley	9.5%
Ground maize	9.5%
Meat and bone meal (45% protein)	9.5%
Dried skim-milk	7.0%
White fish meal (60% protein)	4.7%
Dried yeast (40% protein)	1.7%
Sodium chloride	0.5%
Cod-liver oil	0.5%

In more recent experiments 92 rats have been maintained for ten months on the vitamin-A-rich diet throughout, with the addition of heated lard (350° C. for one hour or 220° for about twelve hours). No pathological lesions of the stomach have been observed among 10 that have died. *In vitro* tests for vitamin A in mixtures of cod-liver or halibut-liver oil and heated fats dissolved in chloroform were carried out to see whether any direct neutralization occurred, but the usual antimony trichloride blue reaction could not be observed, as the heated fats alone gave a brilliant red colour reaction with this substance. Attempts to separate the vitamin A from the heated fats after mixture were not successful, and it is not certain at present whether any direct destruction of vitamin A by heated fats occurs or whether the vitamin reaction is merely masked by the intensity of the red colour reaction. Further work is being done to clear up these points and to determine the nature of the substance in the heated fat responsible for the red colour reaction with antimony trichloride.

Discussion

The foregoing evidence suggests that there is present in repeatedly heated fats a factor which interferes in some way with the absorption or metabolism of vitamin A. Our results confirm Roffo's claim that heated fats cause papillomatosis in the fore-stomach of rats, but no evidence of glandular tumours or of sarcoma has been found. One rat developed a carcinoma of the lower lip, but the significance of a single case cannot be assessed.

Although no recognizable carcinogenic hydrocarbons were formed in heated fats under the conditions of our experiments, a factor which may provisionally be termed "anti-vitamin A" was produced, and the subsequent pathological lesions developed by rats and mice receiving this factor with an otherwise adequate diet were apparently due to an artificially induced avitaminosis-A. Thus our results correlate those of Cramer and of Passey with some of the results observed by Fibiger and by Roffo. The malignant tumours originally described by Fibiger and the more extensive series of Roffo may have been due to the action of some hitherto unrecognized factors in the presence of avitaminosis-A. Mice were less susceptible to induced avitaminosis-A and papillomatosis than rats.

So far as any application of these experiments to human pathology is concerned there is no evidence of the development in fats, under ordinary cooking conditions, of any known carcinogen, but the anti-vitamin-A factor may possibly be detrimental to health, particularly when the dietary intake of vitamin A is low. If there is any analogy between rats and humans in this respect the addition of vitamin A to the diet in the form of raw carrot seems to be sufficient to counteract the effects of the anti-vitamin. The habit of eating raw carrot seems to be prevalent at the present time, and it is possible that future statistics will show whether this has any influence on the incidence of human gastric diseases.

Summary

Groups of rats and mice were fed with a variety of repeatedly heated fats in addition to an adequate basal diet. Within a year signs of avitaminosis-A appeared among the rats, and cases of ulceration and papillomatosis of the fore-stomach were observed among those that died. Control animals fed with unheated fats and the same basal diet showed no gross pathological lesions. Extracts of the livers of rats fed with lard heated under various conditions in addition to the basal diet contained reduced amounts of vitamin A as compared with controls.

The heated fats did not contain recognizable amounts of any known carcinogen, but they included some substance which interferes with the antimony trichloride reaction for vitamin A, giving a bright red coloration.

Rats fed with repeatedly heated fats in addition to a diet rich in vitamin A (carrot) showed no gross pathological lesions in fore-stomach or reduction in liver vitamin A.

The mechanism of papillomatosis in these experiments seems to be related to an induced avitaminosis-A, due to the presence in repeatedly heated fats of an "anti-vitamin A" of undetermined nature.

We wish to acknowledge the valued help given by Dr. L. Woodhouse Price in dealing with a large number of histological preparations, and by Mr. J. G. Chalmers in examining fluorescence spectra of extracts of heated fats.

CARDIAC MASSAGE FOR IMPENDING DEATH UNDER ANAESTHESIA

BY

HAMILTON BAILEY, F.R.C.S.

Surgeon, Royal Northern Hospital

At every turn and in every walk of life it is becoming increasingly apparent that the only effective method of successfully meeting a sudden unexpected catastrophe is to have a preconceived plan and to be able to put it into action immediately. If that plan is comprehensive, and if it can be executed smoothly, it may succeed. To set the heart beating when, during general anaesthesia, it has suddenly and unexpectedly become still, indeed calls for a clear-cut plan of action, for it ranks even higher than the arrest of serious arterial haemorrhage as the most urgent surgical emergency. I have performed cardiac massage about 40 times. In 13 cases the heart has restarted in earnest; but too often, after giving hope for hours or days, disappointment has been the outcome: only 4 patients have survived.

The special point I wish to raise is that cardiac massage should be resorted to earlier. An analysis of published cases shows that cardiac massage has been relatively more successful when the catastrophe necessitating it occurred during the course of an abdominal operation. It is reasonable to assume that, the abdomen being open, massage was resorted to sooner than otherwise would have been the case. In 3 of my 4 successes the operation in progress was an abdominal one, and in 2 of these massage was conducted through the original laparotomy incision. The fourth, my only non-abdominal successful case, sheds some light on the problem before us.

I had completed the operation of epididymectomy for tuberculosis on a boy aged 12. No anxiety had been experienced. I happened to look through the window of the changing-room, and saw the anaesthetist performing artificial respiration. The child had white asphyxia, and we immediately put in operation the routine of having a timekeeper call out the passing minutes. At three and a half minutes I injected adrenaline into the heart. At four and a half minutes, after hastily scrubbing up, I opened the upper abdomen through a midline incision and performed cardiac massage from below the diaphragm. A full minute elapsed without any response. There was then one beat, a short interval, then three or four beats. The heart then restarted in earnest. By the time the abdomen had been closed with through-and-through sutures some colour had returned to the patient's blanched face, the pulse was full but very rapid, and oxygen was being administered. Next day the patient said he felt well.

On the third day the boy complained of dimness and double vision. On the fourth day he could only distinguish between light and darkness. There were other evidences of serious disturbance of the central nervous system, such as incoordination and some paresis. I am not competent to discuss these neurological manifestations, nor is that the purpose of this communication. Sufficient is it to say that it was obvious that the vital centres had been left too long without a blood supply, and during the period of blindness I wondered whether it would not have been better if the cardiac massage had failed. It was during this period I became determined to advocate earlier cardiac massage. By what I believe to be an unprecedented stroke of good fortune, the patient's vision gradually returned and all other untoward signs disappeared. At the present time he has regained his sight and has quite recovered in all other respects (see photograph).

This case in particular convinced me that, to be permanently effective, cardiac massage must be instituted earlier; three and a half to four and a half minutes ("under five minutes" is the generally accepted standard) is too long to wait. Had the patient not been young I feel tolerably certain he too would have joined the large band of disappointments. Equally am I convinced that if I had made

a stand against intracardiac injection taking precedence over cardiac massage before, I might have succeeded in some of the cases in which I have failed.

This is not a sudden change of front. With each succeeding disappointment I have analysed the details of resuscitation, seeking to improve them. On nearly every occasion I have deplored the time wasted in injecting

adrenaline. Inertia and unwillingness to face criticism have, I fear, been instrumental in my continuing to suggest in the works of reference for which I am responsible that cardiac massage is our last card. I wish to revise that view.

Intracardiac Injection of Adrenaline

Championed particularly by the late Harrington Sainsbury, the value of an intracardiac injection of adrenaline has received, and is receiving, pride of place in attempts to restart the heart's action. A study of the literature will show that the successes which have attended this expedient are in the main cases of cardiac arrest during chloroform anaesthesia. In my experience, not once in more than forty instances has an injection of adrenaline into the heart caused it to restart beating. In one case the prick of the needle as it traversed the chest wall (I do not think the heart muscle had been reached) apparently initiated the resumption of cardiac activity; none of the adrenaline in the syringe was injected. In spite of the fact that in every theatre in which I work I try to impress upon the staff that a "cardiac emergency outfit" should be in readiness, oftener than not several minutes have been wasted in getting together the necessary armamentarium. I suggest that the sterile syringe, a three-and-a-half-inch-long needle which fits the syringe, and a bottle of adrenaline should be kept in a sealed sterile jar on the anaesthetist's table. Here it will be in better keeping, and any benefit which adrenaline holds will still be available. But on the following point I am emphatic: adrenaline should be relegated to a subsidiary role.

Is the Heart Beating?

Those without practical experience of these catastrophes are inclined to pass this question by almost with contempt. On the contrary, so difficult and time-consuming is this all-important question that in white asphyxia the correct procedure is to assume the worst and to proceed with resuscitative measures according to a plan by which confirmation

of the necessity for heroic measures is provided by the most direct means available. I have seen an already over-occupied anaesthetist burdened with this question when all the surgeon had to do was to remove a few abdominal packs and put his finger on the abdominal aorta. It should be obvious that if the operation in progress permits access to a large artery it is the surgeon who should inform the anaesthetist. In the absence of direct access to a large artery but with an operative wound before him, the surgeon can at least state whether there is any bleeding, and in certain instances he may feel justified in cutting a moderate-sized artery in order to obtain the necessary information.

When the integument is intact it is the anaesthetist who must settle this point by the means he thinks best. In my view the carotid pulse is the best indicator. The majority consider that a stethoscope applied to the praecordium is the method of choice. My reasons for devaluing the latter are: (1) the patient's head must be left unattended; (2) artificial respiration must be stopped; (3) on at least three occasions the anaesthetist has left his stethoscope in the anaesthetic room, and twice the courier sent for it has returned empty-handed; (4) with the spectre of the coroner before him and the knowledge that by applying the stethoscope he is preventing the continuation of artificial respiration, I submit that even a cardiologist might be unable to answer this all-important question with assurance.

Distribution and Duties of Personnel

With but three to three and a half minutes at our disposal each must know his or her duty: providing they know exactly what to do, even semi-skilled and unskilled members of the theatre team can perform most useful parts.

Timekeeper.—In 1927 I suggested that a junior nurse, a student, or a porter should be detailed to cry loudly each passing minute from the time the anaesthetist sounds the warning note of danger. This plan has proved invaluable, for anxiety masks a correct estimation time.

Provider of Hot Packs.—If in addition to a timekeeper there is a junior nurse available, her duty should be to get a bowl of really hot water and some packs, and be prepared to place the packs, wrung out in hot water, on the praecordium at frequent intervals while the artificial respiration is in progress. This worker is not essential. She should go about her duties without asking questions or distracting the attention of the theatre sister. Her services should be at the disposal of the surgeon's assistant if he should require them.

The surgeon's assistant is dismissed immediately by the surgeon, and relegated to the sole task of performing artificial respiration under the direction of the anaesthetist. He carries out Sylvester's procedure—if necessary, single-handed—but sends for the most suitable helper available.

The theatre sister comes forward and takes on the duties of the surgeon's assistant. Her essential objective is to have in readiness the simplest requirements for a mid-line upper laparotomy.

The anaesthetist takes sole charge of the respiratory apparatus. His first and at all times his most important duty is to be perfectly satisfied that there is a clear airway. His other essential parts can be played without moving from his position at the patient's head.

A (Revised) Plan of Action

Artificial respiration must be started at once, and continued throughout the endeavour. Intrathecal insufflation of oxygen and CO₂ is the ideal form of artificial respiration. Sylvester's method is efficient if the airway is kept clear.

FIRST MINUTE

Anaesthetist.—Clears airway; tilts the table, even slightly, so as to lower the head; breaks a capsule of amyl nitrite under the patient's nostrils.*

Surgeon.—Appoints a timekeeper; dismisses his assistant; with the help of the theatre sister, attends to his operation so that it can be abandoned temporarily; if possible, directly palpates a large artery.

SECOND MINUTE

Anaesthetist.—Administers oxygen; passes an intratracheal tube if circumstances permit and he is particularly skilled in this manœuvre.

Surgeon.—Supervises sterilization of the skin of the upper abdomen and lower thorax while he scrubs up or changes his gloves, as necessary.

Theatre Sister.—Prepares the skin of the upper abdomen and lower thorax.

THIRD MINUTE

Anaesthetist.—If asked to do so, palpates the carotid artery; when free from duties of the second minute opens the cardiac emergency jar and places it within reach of the theatre sister.

Surgeon.—If the information received is that the heart is not beating, makes an incision in the midline through the linea alba, large enough to insert the hand; starts cardiac massage from below the diaphragm, at first with a quick forcible movement for half a minute—the base of the left hand over the lower thorax aids in the manœuvre: if there is no response after thirty seconds, changes the movement to a slower rate of about eighty per minute.

Theatre Sister.—Fills the syringe with 1 c.cm. of adrenaline and fixes the needle firmly to the barrel.

FOURTH MINUTE

Surgeon.—Removes his left hand from the thoracic wall while the adrenaline is injected into the heart by the anaesthetist; immediately afterwards, with renewed hope, continues massage as in the first instance—i.e., quickly.

FOUR-AND-A-HALF MINUTES

Surgeon.—Detaches diaphragm from left costal margin with a stroke of the scalpel; opening stretched to take hand; rhythmically squeezes the heart within the pericardium (this seldom fails to give at least a temporary response).

If the last manœuvre is successful the opening in the diaphragm must be closed with catgut stitches. It is quite sufficient to close the upper midline incision with strong interrupted through-and-through sutures traversing all layers.

Conclusion

I have avoided detailed reference to the literature, not from any wish to minimize the contributions of others, but to simplify the message I would convey. Since Darling and Lane published the first successful case in 1902, I was surprised to find that only 50 permanently successful cases had been reported. In several of these both adrenaline and cardiac massage had been used. It would appear that the combination is useful. One case in particular supports this hypothesis; for after two minutes of massage with no response, adrenaline followed by more massage resulted in recovery (Fiddian, 1936).

"Massage—adrenaline—more massage—supradiaphragmatic massage" is, I believe, the watchword which will save more patients. Massage—earlier massage—is the life-giver; adrenaline is its handmaiden.

* This valuable suggestion was made by Primrose (1935); the object of administering this drug is to distinguish between cardiac depression and cardiac arrest.

"BLUE DRUM," OR IDIOPATHIC HAEMOTYMPANUM, IN CHILDREN

BY

J. H. O'DONNELL, M.B., Ch.B., D.L.O., F.R.C.S.

Aural Surgeon to the Leicester Education Committee; Chief Assistant, Ear, Nose, and Throat Department, Leicester Royal Infirmary

Shambaugh (1929) has given a detailed description of a condition which he has named "blue drum," and of which he reports two cases occurring in adults. Fowler (1939) also quotes a case, but the age of the patient is not specified.

In appearance the tympanic membrane is blackish blue over the whole of the pars tensa, which is retracted. The pars flaccida does not share in the discoloration. The landmarks of the drum stand out clearly, and the condition is not associated with any myringitis or bulla formation.

"Blue drum"

Deafness of the conductive type is present. Two instances of "blue drum" have been encountered recently in children, and a summary of the histories may be of some interest.

Two Case Records

Case 1.—This patient, a girl aged 7, had a history of intermittent deafness associated with colds, occasional earache, but no otorrhoea. During the fortnight preceding examination the deafness had become much worse, although there were no local or general signs of an inflammatory condition. Slight tinnitus was complained of. Examination of the right ear showed that the tympanic membrane had an intense blackish-blue appearance, as described above. The landmarks were readily visible, and there was no bulging. Rinne's test was negative for the C to c' forks, and Weber's test showed lateralization to the right. Inflation by catheter revealed some Eustachian tube obstruction, and rales were heard through the auscultation tube. The drum assumed its normal position after inflation, and the colour changed to a dull grey, with brownish patches. (Shambaugh's cases showed no change in colour after politizerization.) The hearing for the whisper improved from 6 inches to 10 feet, normal audibility being 20 feet. The left ear had a retracted membrane, with a little fluid exudate of a clear character in the lower part of the tympanum. There was a conductive deafness of a less degree than that of the right ear, the whisper being heard at 2 feet before inflation and 12 feet after. The tonsils showed some evidence of infection, and there was a moderate adenoid pad.

After an interval of a few days the right drum was in its initial state of "black-blueness," although the hearing had become a little better (whisper, 2 feet). Subsequent inflations by Politzer's method over a period of some weeks resulted in an improvement of the hearing to 10 feet for the whisper, at which standard the hearing acuity remained stationary. The drum always reverted to its previous blue appearance in the intervals. This is in line with Shambaugh's experience of recurrence, although in his cases inflation was preceded by myringotomy.

Removal of the tonsils and adenoids was then carried out, and fourteen days afterwards both drums were normal in appearance and the whisper was audible at 20 feet in each ear. The condition has not recurred in the several months which have elapsed since the operation.

Case 2.—A boy aged 10 was referred for the removal of tonsils and adenoids. Some slight deafness had been noticed

at home. Examination of the right ear showed a typical blue drum, with a fairly high degree of conductive deafness (whisper, 2 feet). The left drum was a little dull and retracted, and the hearing for the whisper was 10 feet. Fourteen days after the removal of the tonsils and adenoids the blueness was found to be confined to the anterior half of the drum and the whisper was audible in the affected ear at 16 feet. One month after the operation the drum was normal, as was the hearing to voice and tuning-fork tests.

Commentary

Shambaugh's cases occurred in individuals over 50 years old. The treatment consisted of myringotomy, followed by inflation, which expelled a chocolate-coloured fluid. The period of relief was only temporary, and recurrence followed. Fowler's case had an effusion into the maxillary antrum on the side of the ear lesion, but the subsequent course of the case is not mentioned.

It would appear that the condition is the result of a "hyperaemia ex vacuo," consequent on Eustachian tube obstruction. The reported cases recovered readily and completely after the removal of the primary cause of the Eustachian block.

Medical Memoranda

Lung Collapse after Eye Operation under Local Anaesthesia

It is thought worth while recording this case, as a search of the literature failed to reveal a similar one. It is well known that collapse of the lung, both massive and partial, follows all types of surgery, occurring in about 0.3% of all operations, and that various reasons have been assigned for this. It seems certain, however, that it is not entirely due to the irritant effect of inhalation anaesthesia, causing a mucous secretion which, by becoming inspissated, finally blocks a bronchus. There are still many cases of this complication following operations with regional block local anaesthesia, although they are only about one-tenth as frequent. This compares favourably with spinal anaesthesia, in which, as regards abdominal cases at least, collapse is as common as with inhalation. In the following case the only explanation as to causation that can be suggested is that patients with glaucoma are nursed upright after operation and instructed at all costs to avoid coughing. This would tend to allow any mucus to gravitate towards the lower lobes and to accumulate there.

CASE REPORT

A spinster aged 65 was trephined by Mr. Tait of Windsor for a chronic glaucoma on December 23, the anaesthetic being a simple instillation of a few drops of 1% pantocain into the right eye. The local and general condition made satisfactory progress until January 1, when there was a sudden onset of dyspnoea, with pain in the right lower chest. I was asked to see her, and found signs suggestive of partial collapse of the right middle and lower lobes. Although there were no constitutional disturbances suggestive of lobar pneumonia she was given a short course of sulphapyridine, 7 grammes in all. Within a further twenty-four hours there was a complete collapse of the two lobes, as shown by the absence of the respiratory murmur, and a temperature of 100.2°. Postural drainage and bronchoscopy were both contraindicated by reason of her eye condition, so inhalation of carbon dioxide was tried, and although after one period of hyperpnoea crepitations were heard over the affected area the condition remained quite stationary.

By January 6 the patient was feeling fit enough to travel by car to spend a few days in a convalescent home. A radiograph taken on January 7 showed the typical appearance of collapse. She then rested a fortnight, with some pain at the right base for the first few days and with some dyspnoea on exertion. During this time large doses of ammonium carbonate were given

by mouth by her own doctor, and when she was seen on March 6 the condition, as judged by physical examination of the chest, had completely cleared.

ROGER LANE, M.B., M.R.C.P.

Treatment of Post-anal Dermoids

It has been found difficult to ensure healing by first intention in wounds following radical excision of post-anal dermoids. Adipose tissue in this region is particularly unsuitable for dealing with post-operative collections of blood and exudate and in maintaining a clean field for healing.

By exposing muscle in the floor of the wound it was hoped that drainage and other factors which influence healing would work to better advantage. The fascia covering the sacral and coccygeal origins of the glutei maximi is exposed by wide excision of the dermoid region, and a piece of the fascia about the size of a halfpenny is easily removed from one or both sides (see Fig.). This was done in 4 consecutive cases of excision of

infected post-anal dermoids, with closure and healing by first intention. All 4 patients were women: 2 had had exacerbations of swelling and pain within the two weeks preceding operation, and 2 had had previous incisions. All have remained healed for from six weeks to seven months after operation.

Apart from excision of the fascia the operative technique was essentially as that described by W. B. Gabriel (1937). Haemostasis was obtained by pressure and a few fine catgut ligatures. Dead space was reduced by deep silk-worm-gut sutures tied over a roll of gauze. The patients were nursed on their side in bed.

Final conclusions cannot be drawn from so small a series. However, the principle of including healthy muscle in the healing process has not done any harm and may be worthy of extensive trial in suitable cases.

Appendix Strangulated in Congenital Hernial Sac in an Infant

The following case may be of interest in view of the age of the patient, the nature of the contents of the hernial sac, and the fact that, though the hernia was of eight hours' duration only, operation showed that it would not have been wise, and hardly possible, to reduce it by taxis.

A baby aged 5 weeks, suffering from convulsions, was under the care of Dr. Mackay at the Queen's Hospital for Children, London, E., when he suddenly developed a swelling in the right inguinal region and scrotum. This, when examined eight hours later, was found to be a scrotal hernia. The scrotum was red, inflamed, and oedematous. The temperature was 99° F., pulse 132. The child vomited once during examination. The bowels had not moved since the appearance of the hernia. An attempt at taxis being unsuccessful, operation was undertaken.

Local anaesthetic 1% novocain was employed and the sac exposed by the usual incision. It was bluish black in colour, and when opened dark fluid poured out. The vermiform appendix, stretching from the internal abdominal ring to the scrotum, was

now seen as the hernial content. It was gangrenous throughout and adherent to the sac posteriorly. The constricting agent the internal abdominal ring. This was enlarged by dividers in an upward and outward direction. The caecum now pressed and it was seen that the constriction occurred exactly at the junction of the appendix and caecum.

The appendix was amputated, but the sac, being inflamed and adherent, was not further interfered with. Two catgut sutures were used to unite the divided internal oblique and transverse muscles; the mouth of the sac was closed at the internal abdominal ring with a few sutures, and the internal oblique e united with continuous catgut. The skin edges were coapted interrupted "kalmerid" suture. The lower end of the wound was drained with a dozen strands of silk.

The baby made an uninterrupted recovery: the skin sutures were removed on the eighth day, and the wound was completely healed in ten days.

I have to thank Dr. Mackay for permission to publish this case.
London, E.2. T. O'NEILL, M.D., F.R.C.S.

Observation of Malaria Parasites in Fresh Blood Films

When fresh blood is sealed beneath a cover-slip changes occur which are not obtainable when blood is smeared directly on a slide. In some cases of malaria one of these changes is engulfing of a malarial parasite by an amoeboid white cell. Such a process is often seen in a fresh film in which crescents abound in the blood stream. If this process be allowed partly to occur and then stained the resulting change should be demonstrable.

A fresh film was made, and after three to five minutes the cover-slip was slid away from the slide. Apart from microscopic forms it was evident that the hoped-for result had been achieved, for a "crescent," now in spheroidal form, was actually in contact with a white cell, into which had passed some of the granules of the crescent.

The crescent was stained blue with cobwebby protoplasm, granules, 32 in number, being black. The white cell had a small lobed palette-like deep purple nucleus, its protoplasm being pink and cobwebby; in it were eight or nine granules, similar in form and colour to those in the crescent. Between the blue protoplasm of the crescent and the pink protoplasm of the leucocyte there was no demarcating border. It looked as if the white cell's meal was severely distending its outline.

When a crescent is approached by a leucocyte in the living blood it is apt, as if under sentence of death, to perform the most intense gyroscopic movements, its black granules being centrifugalized at a great pace. This revolving globe only half its red cell.

A similar object was obtained in the stained film after a few minutes life under the cover-slip. A ring of black rods, smaller than a red cell and corresponding to the globe mentioned above, was arranged circumferentially like a ringlet of hair. Inside and not completely filling it was a purplish-blue cobwebby mass while outside the ring there was a splash of blue which with streaky short circular lines seemed to have been put into sort of rotary movement by the gyroscopic globe it contained. It looked then as if one of these rotating bodies had been caught at a lucky moment.

C. A. VAN ROOYEN, L.R.C.P., M.R.C.S.
Undugoda, Ceylon.

P. Cohen, M. Weichsel, M. and J. H. Lapin (*J. Pediatr.*, 1940, 16, 30) record their observations on 432 whooping-cough patients treated with various therapeutic agents. Vaccine treatment, which consisted of Krueger's vaccine, Sauer's vaccine, toxin vaccine, or Bordet vaccine, did not improve the symptoms but was even associated with attacks which were severer than those of the 80 controls. The results obtained with the topagen (soluble protein of *H. pertussis* in normal saline) topagen hypodermically did not differ from those of the controls. Patients treated with convalescent serum and hy immune serum had fewer coughing spells, a shorter period of illness, and greater freedom from complications, but only if the serum was injected before the paroxysmal stage.

Reviews

EARLY TREATMENT OF WAR WOUNDS

The Early Treatment of War Wounds. By William Anderson, O.B.E., M.B., Ch.B., F.R.C.S. Oxford War Manuals. General Editor, the Right Hon. Lord Horder, G.C.V.O. (Pp. 96; illustrated. 5s. net.) London: Oxford University Press. 1941.

The Oxford War Primers gained no little popularity in the last war and covered a wide field of interest in medical and surgical problems. Here is the first of a corresponding series designed to bring certain subjects up to date. This volume is compact in form, well printed on good paper, and sells at a moderate price. The author frankly bases his views on practical experience gained in 1914-18, but he has not failed to consider any relevant advances in wound treatment which have been made since that date.

The first chapter deals with surgery in advanced units, and shows a clear perception of what is practicable in that zone. The advice given conforms to current practice in the British Army, and is direct and simple. The only criticism of detail which might be made is his recommendation of splints for fractures of the humerus, which depend for their action on an axillary crutch; many have found these splints to be uncomfortable and not as effective as a simple cradle application of Cramer wire in the transport period. In subsequent chapters various sections of work at the casualty clearing station or corresponding unit are considered. In discussing the use of fluids for intravenous transfusion the author does not appear to have made use of the up-to-date information on the subject to be found in the M.R.C. Memorandum on Wound Shock; nor does he recognize that an efficient blood transfusion service has been in being since the start of the war. The general principles of early wound management are admirably stated, and useful practical hints are given both in this chapter and in the remaining sections. The chapter on penetrating wounds of the abdomen is a model of compact statement and contains a wealth of sound advice. The treatment of burns is not considered in this volume, as the intention is that this subject should be dealt with in a separate manual.

This little book should be of help to every medical officer serving in the Army, as a commentary on the *Training Manual* and other standard works.

A MONOGRAPH ON SCABIES

Scabies—Civil and Military: Its Prevalence, Prevention and Treatment. By Reuben Friedman, M.D. (Pp. 276. \$3.00.) New York: Froben Press. 1941.

It is a sign of the times that a monograph on scabies should now be published, and medical practitioners and the public health services have reason to thank Dr. Reuben Friedman for his timely reminder of a disorganizing disease, the effects of which have again and again been recorded, and again and again been forgotten. The book in question, entitled *Scabies—Civil and Military*, gives us many examples of the formidable consequences of scabies in the past, and up to—and beyond—the war of 1914-18, when, in one British Army, skin diseases were responsible for 90% of the sickness rate. While statistical tables are to be seen on many pages, this book is far from a dull compilation of figures. Dr. Friedman enlivens his story with many a glimpse into the past. Thus, whether it be fact or legend, it is believed that even the great Napoleon fell a victim of the prevalent scourge; and that in his campaigns, as Sokoloff relates, whole regiments, officers and men, on reaching camp would throw off their equipment

and scratch en masse, their commander-in-chief scratching himself with a vengeance until blood appeared.

The reader will turn with particular attention to the sections on the prevention and the treatment of scabies. The author's views on prevention are summarized as follows: (1) personal cleanliness, (2) early diagnosis and treatment, (3) detection of and treatment for infected contacts, (4) disinfection of the fomites. With these admirable directions every dermatologist will be in complete agreement. Dr. Friedman devotes 85 pages, divided into five chapters, to the treatment of scabies. In spite of the well-founded knowledge, long possessed by the peasantry, that external agents cured the disease, the medical writers of antiquity found the cause of scabies in a melancholy humour, in black bile mixed with irritating phlegm, and, even in Van Helmont's time, in acrid or irritating salts contained in the serum or lymph. It was against these theories that Bonomo had to contend, to establish his heretical belief that scabies was of parasitic origin and was cured only by the use of externally applied remedies (p. 194). For this purpose sulphur in some form has long been the accepted agent. Sulphur, however, has certain disadvantages which, in the reviewer's belief, are proportionally diminished as the experience of the practitioner grows. Nevertheless, we may well look to modern therapy to devise remedies which, without reducing efficiency, cut down the time factor; and, as a further step, are not greasy and are odourless. Benzyl benzoate, and more recently rotenone, a derivation of derris root, seem to satisfy these conditions. With other preparations they and their application are fully and critically discussed in the text.

This is an admirable book to which the author has clearly given much of his time and attention: an outstanding contribution to a subject which will become of more and more importance. It may even suggest to the responsible authorities in this country that something should be done to control a rapidly growing menace.

CARE OF THE MOTHER

Babies Without Tears. By Dr. Edith Summerskill, M.P. (Pp. 158. 6s.) London and Melbourne: Hutchinson and Co. (Publishers), Ltd.

This book has a noble theme to commend it. The relief of pain in childbirth and the provision of adequate facilities to prevent the terrible waste of life that still occurs are aims worthy of a crusade, but the conduct of such a crusade is neither easy nor free from danger. To write a book "for all mothers, expectant mothers, doctors and midwives" is a task that few doctors would care to undertake, and still fewer could accomplish with success. Dr. Summerskill has been unfortunate, or subtle, in her choice of title, which may refer to the eye or the perineum with equal justification, and the claim that the book presents a cogent and authoritative plea for the use of anaesthesia is open to criticism. The broad facts of the case, which few will dispute, are that unnecessary suffering can be and should be prevented, and that efficient obstetrical services would reduce the present loss of life. The urgency of the plea is for progress to be expedited.

By her handling of the subject the author has appealed more to the lay public than to the medical profession, and in doing so she has at times been unfair to both. The far-reaching effects of the cumulative influence of the Royal College of Obstetricians and Gynaecologists have not been mentioned, although it is through the activity of the college that the desired goal will almost certainly be reached. The lay reader unacquainted with the facts would believe from Dr. Summerskill's book that progress is delayed because of the callousness of man, be he doctor or politician, to the sufferings of women. This is contrary to fact and

savours of political agitation, which should have no place in even a pseudo-scientific publication. The lament that midwives are not taught to give anaesthetics and "repair any tear of torn tissues" is strange when one considers the serious implications of such a policy and realizes that it is sponsored by an advocate of safer motherhood. Readers are asked to believe that Vera Brittain's harrowing description of the confinement of Janet gives a fairly realistic picture of childbirth without an anaesthetic, and are told that every doctor knows there is nothing exaggerated in this description. This is but one example of the overstatements which weaken the value of the book, for if the author believes what she asks others to believe her experience of obstetrics cannot have been wide and must have been unfortunate. Dr. Summerskill's crusade is noble in purpose but faulty in execution.

A BOOK OF VERSE

Childhood and Other Poems. By Sir G. Frederic Still, K.C.V.O., M.D. (Pp. 152. 5s. net.) London: John Murray. 1941.

That this slender volume of verse is now available to a wider public than was the original intent of their author is a matter for congratulation, and we are glad that the counsels of those friends for whom they were first of all privately printed have prevailed. "An artless song—Tuned like some old-world melody to themes of quaint simplicity"—thus does Sir Frederic Still at once define his sense of poetry and what the reader may expect to find. And in the frank simplicity and sincerity of these little poems there is solace in these days which are harsh for the gentle of heart. More than this, the reader may if he will learn much of the writer, for in each "artless song" there is apparent the clear-sighted observer of childhood who sees with a depth of affection but who sees clearly; and a man at peace amid "books and the running brooks." Nowhere does he point a moral, but inherent in his writing are the beauty and satisfaction of truth and love and duty. The dedicatory sentence, "As one that gleaneth after the grape gatherers," is of a characteristic modesty, since it is clear that Sir Frederic venerated the masters who have caused our English tongue to sing and was well aware of his indebtedness. In short, this is a little book blessedly free of whimsy in which it is clear that to the author children and Nature were best evidence of "the day-spring from on high."

We had written thus far when came the sad news of the author's death, which deprives medicine of a singularly gracious influence. As if in anticipation of his approaching end he expresses the hope in one of his last poems

That so of me.

Shall nothing live that might work other's ill,
No legacy

Of harm to lead one single soul astray,

Thus may it be,

When I shall die.

That wish is fulfilled.

Notes on Books

The Ministry of Health has issued a booklet which is Part I of Emergency Medical Services Instructions and deals with medical treatment in special centres. It is pointed out in a foreword that the instructions have reached such proportions that it has become difficult for those who have to carry them out to see that this is done. The wise decision has therefore been made to consolidate these instructions into booklets, a step which will be welcomed by those whose desks are now beginning to be piled high with leaflets of every description. The booklet just issued covers all the separate instructions on

medical treatment and special subjects issued as E.M.S.I.s: E.M.S. Gens. from the beginning of the Emergency scheme until the end of May, 1941, with the exception of E.M.S.I.s 1278, and 289. Subsequent amendments and additions will be issued in bulletin form from time to time. The booklet consists of sixty pages, and a detailed contents list makes it easy to find one's way about. The booklet is not on sale generally but is issued to officers of the Emergency Medical Service only.

An Index of New Remedies, by Mr. W. MAIR, contains a list of recently introduced remedies, together with short notes on the therapeutic purposes for which they are recommended. The desire of manufacturing firms to label their products with names registered as trade marks has always been a major obstacle to the development of any rational nomenclature for new drugs. The situation has been aggravated recently, and in some cases dozens of new names have been devised for the description of a single drug. For example, the index gives a list of 33 proprietary names for sulphanilamide. It is obviously impossible for medical practitioners to keep abreast of nomenclature of such crazy complexity: hence this index is a very useful work of reference. It will at least enable the practitioner to know whether a new name refers to some important therapeutic advance or is merely one more unnecessary ally of some well-known compound. It is published at 1s. 6d. free by the *Scottish Chemist*, 240, Albert Drive, Pollokshields, Glasgow.

A textbook which reaches a seventh edition evidently appeals to the medical public. Prof. LOGAN CLENDENING'S *Methods of Treatment* (Henry Kimpton, 25s. net) now appears with collaboration of Dr. HASHINGER as editor, and with the help of twelve associates on special subjects is an excellent introduction to modern therapeutics. As before, the first part describes the physician's armamentarium not only of drugs, diet, hydrotherapy, and physical therapy, but also the minor surgical procedures of treatment, such as venesection and blood transfusion, spinal and cisternal puncture, thoracentesis and gastric lavage. The second part is devoted to special discussion of therapeutic measures in particular diseases, and the practitioner will find a readable and reliable account of treatment of the system diseases. Tropical diseases are not included under a separate heading. The editor has a strong bias towards the physical aspects of medicine; not that he neglects the neuroses and psychoneuroses, but he takes what might be regarded as the practical view in discussing and treating them. The physician is to demand of himself the answer to the question, Why is this man unwell? The individual may have a body which in some way is a drag, or may find the conditions of living and work difficult. Treatment, then, of the psychoneuroses involves taking account of all these aspects of the patient and all aspects of his work, and endeavouring to establish the patient's relations with reality. Throughout the author introduces appropriately a useful and interesting historical background by quoting classical descriptions of original observers—for example, Wittich on digitalis, and Bodington on rest and fresh air for tuberculosis. This book of a thousand pages is worthy of a place on the practitioner's consulting room and will attract and delight by the racy character of the instruction.

Preparations and Appliances

QUININE DIASCORBINATE

Orgakinine (Organon Laboratories, Ltd.) is a new synthetic compound—namely, quinine diascorbinate. It is prepared in ampoules for injection and in tablets for oral use. The tablets each contain 36 mg. of quinine base and 39 mg. of ascorbic acid. The manufacturers quote evidence in support of the view that fevers cause loss of ascorbic acid. Parenteral administration of orgakinine is suggested as an improvement on the traditional method of quinine therapy in lobar pneumonia. The tablets are recommended for treatment of colds and influenza. The suggested dosage of six tablets a day would provide about 216 mg. of quinine and 0.2 gramme of ascorbic acid.

SATURDAY JULY 19 1941

PHARMACY AND MEDICINES BILL

A leading article in the *Times* the other day cited the new Pharmacy and Medicines Bill, which received a second reading in the House of Commons on July 8, as an example of hurried wartime legislation. True, the reasons given by the Chancellor of the Exchequer, in his Budget statement, for proposing to take up Parliamentary time just now with a Bill to repeal the Medicine Stamp Duties were hardly convincing. Doctors did not need to be reminded that the Medicine Stamp Duties had become "administratively unworkable" and were largely ineffective in controlling the sale of "quack" remedies, nor were they much concerned with the fact that the Purchase Tax on medicines created the anomaly of a tax on a tax. They were concerned, however, lest the Bill should, in the absence of clauses controlling the sale and advertisement of proprietary medicines, undo even the little that has so far been achieved and encourage the indiscriminate sale and purchase of secret remedies. But the Bill now before the House allays many of these early fears and even promises a greater measure of control than hitherto. It is well known that the medical profession would like to see put into operation all the recommendations of the Select Committee on Patent Medicines of 1914, but experience has shown that such an ideal cannot be attained in one step. The new Bill—admittedly piecemeal legislation—will, if it becomes law, make a useful beginning and pave the way to eventual full control.

Briefly the Bill makes it illegal to advertise remedies for the relief or cure of Bright's disease, cataract, diabetes, epilepsy or fits, glaucoma, locomotor ataxy, paralysis, or tuberculosis, or substances to procure miscarriage. Exceptions are made for advertisements published by a local authority or voluntary hospital or in journals of a technical character for circulation to doctors and other professional classes. The diseases named are substantially those proposed by the Select Committee. The prohibition does not apply, however, to surgical appliances, deaf aids and similar articles, or to articles offered for the cure of habits associated with sexual excess or indulgence. The Bill also forbids the retail sale of medicines on or after January 1, 1942, without the disclosure on the container, wrapper, or label of their composition or active constituents either in specific terms or by reference to the *British Pharmacopoeia* or the *British Pharmaceutical Codex*, unless the medicine is prescribed for the needs of a particular person and supplied for his own use. (This follows the recommendation of the Select Committee.) After September 2, 1941, articles recommended as medicines may not be sold retail by any person who is not a registered medical

practitioner, a dentist, an authorized seller of poisons, or a person who has served an apprenticeship and is carrying on business as a druggist at the date of the passing of the Act.

So far so good, but if the provisions of the Bill are to be effective there must be some means of enforcing them, perhaps in the same way as the Food and Drugs Acts are enforced, with an Advisory Committee to watch over administration. Further, it is not sufficient to disclose only active ingredients; as Sir Francis Fremantle pointed out in the debate, not only should all ingredients be named but the quantities should also be stated. Nor does the Bill say how the ingredients should be described. The disclosure might be in such pseudo-scientific terms as to constitute no disclosure at all. This clause of the Bill, to achieve its purpose, should make it compulsory to describe the ingredients in common terms readily understood by the general public. Finally, it is regrettable that there is no control of what may conveniently be termed "fear advertising"—that is, of advertisements which seek to persuade the public that they may not be so well as they feel. It is to be hoped that these matters will receive attention during the passage of the Bill through Parliament.

HYPOCHROMIC ANAEMIA

The criteria by which authors have collected cases of idiopathic hypochromic anaemia have often been biased by a special interest in individual symptoms such as achlorhydria or dysphagia; and anaemias due to malnutrition or pregnancy have been included in spite of evidence that the anaemia was normocytic. If hypochromic anaemia is to be characterized at all it must be on the basis of the anaemia, and hypochromia must signify that the red cells are incompletely filled with haemoglobin. Ideally it would be defined in terms of mean corpuscular haemoglobin concentration, or the ratio between the haemoglobin content and the mass of the red cells, but such measures require a centrifuge and are likely for some time to be omitted in routine blood examinations. Lundholm¹ therefore quite simply defines hypochromic anaemia as anaemia with a colour index less than 0.75. Although hypochromic anaemia is usually curable by iron, it is by no means synonymous with iron deficiency, for there is no doubt that iron deficiency can exist without anaemia.²

Lundholm's material comprised 306 cases, of whom 201 came to hospital for treatment of their anaemia, 71 were discovered incidentally, and 34 were discovered on examining relatives of the patients; 92% were in women. Lundholm stresses the diagnostic value of the typical facies, by which he means an aged, sallow, wrinkled face which often contrasts with a smooth, white, and transparent body skin. We need not go into his analysis of the haematological data, but will give his figures for the common clinical symptoms, which are achlorhydria (Ewald) in 67% of cases, glossitis in 44%, koilonychia in 42%, typical facies in 35%, Plummer-Vinson syndrome in 19%, and splenomegaly in 9%. These symptoms were all commoner in the more anaemic

¹ *Acta med. scand.*, 1939, Suppl. 102.
² *Ibid.*, 1938, Suppl. 90, 380.

cases, and splenomegaly was uncommon except in the most severe. Achlorhydria is about twice as common as in the ordinary hospital population. Both achlorhydria and the Plummer-Vinson syndrome cause subjective discomfort which induces the patient to seek advice, and they are therefore more common in patients who come for treatment than in those in whom the anaemia is found by chance. It is clear that achlorhydria is neither the cause nor a *sine qua non* of the anaemia. As achlorhydria is more common when the anaemia is severe, and probably also when it is of long duration, and as a number of the patients lost their ability to secrete hydrochloric acid while under observation, Lundholm is inclined to believe that the anaemia may gradually cause such changes in the mucous membrane of the stomach as result in achlorhydria. The latter may therefore be temporary and reversible to begin with, but later becomes permanent. An alternative hypothesis is that both anaemia and achlorhydria are the result of iron deficiency.

Working with a fairly homogeneous population whose daily intake of iron averaged about 9 mg., Lundholm could find no correlation between diet and anaemia in individual cases. He reviews the various iron-balance experiments recorded in the literature, and shows that the results are often discordant and do not stand close scrutiny. A negative balance of only 1 mg. iron a day would mean the loss of 10% of the body's store of iron in a year; but the relative inaccuracy of the chemical methods, the great variation in the iron content of food-stuffs, the difficulty of differentiating the amount of faeces derived from a given diet, and the inaccuracies in sampling the diet and the excretions, all render it doubtful whether this degree of accuracy can be attained in balance experiments. He concludes that dietetic conditions alone are not a sufficient explanation of the anaemia, nor is it due to the loss of iron in menstruation and pregnancy, for there is no difference in these functions between the anaemic women and those who remain normal. These are merely predisposing factors, and the fundamental fault appears to be a difficulty in absorbing iron from the food or in mobilizing it from the depots. He suggests that this is an inborn error of metabolism, and calls the disease hereditary hypochromic anaemia in consequence. This is probably going too far for most people's taste, but it is to be hoped that this unpromising title will not prevent his monograph's being studied as widely as it deserves.

In a much smaller series of women in Newcastle-on-Tyne, Khan¹ has likewise shown that there is no close correlation between the incidence of anaemia and the individual intake of iron. No one can put aside the great mass of data which show that the incidence of anaemia in different peoples, and in different sections of the same people, bears a direct relation to the iron content of the diet, but with iron, as with the vitamins, other factors come into play in deciding which particular individuals will develop a deficiency. Achlorhydria and menstrual losses are obviously not the only factors which may determine the onset of iron deficiency on a given diet, and we can say no more about the other factors except that in some cases they appear to run in families.

AGGREGATION OF TODDLERS

In a recent letter to the *Times* on the provision of nurseries for "under fives," Lady Allen of Hurtwood suggested that "urgent need for the appointment at the Ministry of Health of a second Parliamentary Secretary to initiate experiments to educate the public, and to focus all aspects of this vit work." This is precisely what, for over half a century under the expert direction of the medical officers of health throughout the country, has been a main effort of the public health authorities. During this period a vast amount of fact has been accumulated, and, if public assimilation has lagged, some outstanding principles have emerged for the guidance of zealous but uninformed social reformers. "Under fives" of the toddler period were very well provided for, so far as mere buildings and excellent staffing could do this, in the infant departments of the public elementary schools. Yet, as a result of the experience of medical officers of health and school medical officers this excellent provision has largely been abandoned for the all-important reason that it has been found incompatible with the health of those for whom it was made, and even dangerous to life. At the tender ages of early childhood, human beings, like other mammalian species, cannot be aggregated without grave danger. Susceptible to infections to a degree not experienced by older children and adults, toddlers succumb disastrously when, with aggregation, exposure to infection is increased. They contract infections which in later life might be regarded as minor and die from them at a rate that is higher than at any subsequent age period. These are commonplaces of medical knowledge. Yet with the perversity which in England characterizes so much misdirected effort, expert opinion is flouted or ignored, and uninformed philanthropic enthusiasm displaces an equally well-intentioned yet informed and sane direction. For instance, no sooner had we attended the effort to raise the minimum school age than the nurseries and crèches, subject to exactly the same danger as the infant departments for which they were substitute sprang up like mushrooms everywhere. The fact is that for some children, care and provision other than that of the mother and the family circle is necessary, and it is this residuum that affords at once excuse and incentive for a campaign for publicly provided nurseries and crèche. Compromise with unavoidable evil may be necessary, but it should not be regarded as a virtue. Since already local authorities have covered the ground, experiment by amateurs in so sensitive a field as that of the unmothered toddler is the less permissible. This is no time for ignorance in direction in vital affairs, for by-passing those with knowledge and putting in their place Parliamentary Secretaries who can only properly function when trained and experienced officials continuously inform Ministerial policy. The Ministries abound in technical advisers. Just as in the Army the generals must be unfettered by political interference, so in matters that concern health the medical advisers should not be trammelled by the piling up of Parliamentary Secretaries. Neglect of this elementary principle is bound to yield an aftermath of sickness and deaths which will be revealed in the vital statistics of the coming years. A.R.P. work, uninformed at first by medical direction, has been responsible in certain of its activities for putting back the clock to pre-sanitary days. The nation cannot afford similar mistakes to be made in the care and supervision of infants in the peculiar circumstances of the war. One inexorable fact dominates a situation which is political manoeuvring can ultimately disguise. Aggregation of the young in schools, in hospitals, in nurseries, in crèches is unnatural, and this departure from the normal law of domesticity, wherever necessity has imposed it, has

¹ *Lancet*, 1941, 1, 11.

had unfortunate results. The dangers to the highly susceptible children of tender years are such that aggregation should only be sanctioned when unavoidable, and then it calls for the most skilful and knowledgeable control. Far better to subsidize the mothers within the seclusion of temporary homes, if there be occasion, rather than to employ deputies in institutions. A proposal to withdraw little children from the care of their mothers, to aggregate them in tens, in scores, in fifties, under the care of "suitably trained friendly aliens" or others, in order that mothers may engage in war work should be critically watched by the medical profession. It is on record that in the Franco-Prussian War, during the siege of Paris, the infant mortality of that city fell to a phenomenally low figure. This was a result not of the provision of nurseries to relieve mothers of their duties, or to set them free to discharge others for which they were less fitted, but of an enforced reversion to natural maternal conditions where breast-feeding and maternal care were inescapably imposed. This significant historical fact should be well considered.

SULPHANILAMIDE AND SEAWEEDS

The following formula for a satisfactory base for a sulphanilamide ointment appeared recently¹:

1. Dissolve 10 parts of sulphanilamide in 25 parts of hot water (almost boiling). Filter.
2. To 4 parts of sodium alginate add 75 parts of boiling water, emulsify, and then strain the resulting mucilaginous mixture through fine gauze. Mix the filtered sulphanilamide solution and the sodium alginate while hot, and stir this mixture until cool.
3. Add 16 parts of anhydrous wool-fat, 1 part of sodium chloride dissolved in 4 parts of water, and 78 parts of white petrolatum base to the sulphanilamide-sodium alginate mixture, and mix until smooth.

Subsequently it was stated² that the object of this was to get a base for sulphanilamide and its derivatives which would not be greasy and would be non-irritating. Ointments with a base of hydrous wool-fat or cod-liver oil are not used because they tend to "cake" in the wounds. The ointment described here is smooth. Not only has it been used on surface wounds, but it has proved to be non-irritating and non-toxic when applied to mucous membranes such as the conjunctiva and the sclera and cornea. The use of sodium alginate to economize in substances such as glycerin and tragacanth is of particular interest to prescribers in this country. Sodium alginate is manufactured from seaweed, and is mentioned under this heading in the Medical Research Council War Memorandum No. 3, "Economy in the Use of Drugs in Wartime." It has a formula resembling those of cellulose and pectic acid, and is used in industry for stabilizing suspensions and emulsions, thickening solutions, forming gels, and preparing films and coatings. The main disadvantage of sodium alginate, which has hindered its use as a wartime substitute, is that it is chemically reactive, and on this account it cannot replace glycerin and tragacanth in a number of familiar suspensions and emulsions used in medicine. Occasions on which it can be used should, therefore, be the more thoroughly exploited, and this is especially true of sulphanilamide ointment, which is likely to be prepared in bulk and used on a large scale. The economic importance of seaweeds has recently been discussed by Moore,³ and their uses were described in a presidential address to the Botanical Section of the Southern

Union of Scientific Societies by Miss E. M. Delf.⁴ Seaweeds have at various times been used as foods for animals and man, as manures, and as sources of potash, soda, iodine, and mucilages. In the animal economy they probably have no caloric value, but serve as flavouring agents and sources of minerals and vitamins. As seaweed is relatively expensive to collect, costing from 12s. 6d. to 15s. a ton to gather and cart only a few miles, the seaweed industry in Great Britain languished when cheaper sources of alkalis and iodine became available. In America, too, the large plant at San Diego, designed mainly for the production of calcium acetate, acetone, and cognate substances from seaweed in 1914-18, was dismantled soon after the end of the war. To-day, however, there are increasing uses for colloids and plastics, and the need for these may revive the seaweed industry once more. Seaweeds differ from other plants in that their supporting tissues contain no lignin or cellulose. Instead, the thick-walled mechanical elements are highly mucilaginous, giving greater flexibility and more elasticity than are found in the tissues of higher plants. These mucilages are of two kinds: *agar*, which is produced from red seaweed, and *algin*, which is extracted from brown seaweed. Agar is closely similar to the gelatinous products derived from carrageen or Irish moss (*chondrus*, B.P.C.). Up to date little success has attended efforts to produce a good bacteriological agar in this country, and owing to the scarcity and dispersion of suitable red seaweed it is doubtful whether it can ever become an economic proposition here. The brown seaweeds from which algin is derived are much more abundant, and it is probable that the future will see increasing applications of algin and its derivatives.

MAGNESIUM AND TOOTH FORMATION

Although it has been known for some time that magnesium is a constituent of the inorganic material of teeth, very little experimental work has been done on the effects of a dietary deficiency of this element on the composition and structure of teeth. Watchorn and McCance⁵ produced a partial deficiency in young rats by reducing the amount of magnesium in the diet to forty parts per million. The teeth showed an increased water content, capillary dilatation, and reduction of the magnesium content to about one-half after ten weeks on the diet. According to Duckworth and Godden⁶ a more severe deficiency (only six parts magnesium per million) in young rats resulted in tetany and death from the sixth day of treatment onwards. These rats grew normally, and their incisors increased in weight, but the total amount of magnesium in the teeth remained constant. Hence, since abrasion of the ends of the incisors was continually going on, there must have been some deposition of magnesium during the deficiency period. Meanwhile the magnesium content of the teeth of the control animals fed on a complete diet had increased. During the same period the magnesium content of the femurs of the animals on a deficient diet fell by about 30%. When the rats were again given magnesium, it was deposited in the teeth and femurs at a normal or slightly increased rate. The histological changes in the teeth during the period of magnesium deficiency⁷ involved a change in the calcification rhythm, widening of the predentine, and, in certain parts, shrinking of the odontoblasts. Recovery when magnesium was again given was rapid; the calcification cycle was resumed immediately, the odontoblasts became normal in about six days, and predentine of normal width

¹ *J. Amer. Med. Ass.*, 1941, 116, 356.

² *Ibid.*, 1336.

³ Moore, L. B., Department of Science and Industrial Research, New Zealand, Bulletin No. 25, 1941.

⁴ Delf, E. M., *Proc. Trans. S. U. Sci. Soc.*, 1940, 45, 15.

⁵ *Biochem. J.*, 1937, 31, 1379.

⁶ *J. Physiol.*, 1940, 99, 1.

⁷ *Ibid.*, 99, 8.

was made. The wide pre dentine formed during the deficiency was not altered; it was lost only by the continued growth of the rat's tooth and abrasion of the distal end. The behaviour of magnesium in being withdrawn from the skeleton but not from the teeth during a period of deficiency is similar to that of calcium. Gaunt and Irving¹ showed that calcium and phosphorus were withdrawn from the skeleton more than from the teeth, and Schour *et al.*,² in experiments on the effects of parathyroidectomy, fasting, repeated pregnancies and lactations on the incisors of over 100 rats found no histological evidence of calcium being taken from the teeth. Thus it seems safe to conclude that both calcium and magnesium stay in the teeth when once deposited there. They are not withdrawn from these organs during a sudden acute deficiency in the diet.

INTRAPERITONEAL GLUCOSE

The technical difficulties and the uncertainties of the intraperitoneal route for the administration of fluids have combined to restrict its usefulness, and it is only rarely employed to-day. Totten,³ in a review of the literature on the intraperitoneal injection of hypertonic glucose solution, states that the reports and evidence are confusing and conflicting. Buchbinder, using 20% glucose solution intraperitoneally at intervals, found that encapsulation of drains could be prevented and their patency maintained for several days. At the same time a transudate was formed which prevented not only fibrin formation but also the development of adhesions after chemically induced peritonitis. Where there was infection, however, the intraperitoneal glucose led to a more rapid spread of peritonitis. Totten now records the results of a series of experiments in which 20% glucose was injected into animals by the intraperitoneal route. This injection was harmless apart from a controllable degree of dehydration: there was a rapid transudate which was completely absorbed within twenty-four hours, but no formation or re-formation of experimentally produced adhesions. In the presence of peritoneal contamination the glucose solution interfered with the production of fibrin and hastened the spread of peritonitis. It is well that these findings should be confirmed and restated. The potential advantages of controlling fibrin formation and the development of adhesions by a "wet" peritoneum will be greatly outweighed by the added risks of spreading any infection and of inhibiting localizing processes. The control of infection remains a much bigger problem than the control of adhesions.

VASCULAR SURGERY

The name of Dr. Rudolph Matas is an honoured one in the field of international surgery and of outstanding importance in the sphere of vascular surgery. It is all the more honoured since he started his internship at the Charity Hospital, New Orleans, in the year 1877, at the dawn of the Listerian era, and he is still contributing to the subject he has made so much his own. The unsettled conditions which prevailed in the State of Louisiana during the early part of last century provided surgeons with opportunities for treating many wounds of the peripheral blood vessels and their sequelae. Thus the surgeon's traditional interest in this field was maintained and continued at a time when abdominal and other branches of surgery were

claiming more and more adherents. It is worth remembering that in the past the surgeons who achieved the greatest international fame were those who had won their reputations largely through their own work in the surgery of the blood vessels. Matas's early training and experience were thus in a school where the surgery of vascular lesions was a day-to-day problem. In 1888 he carried out the first endo-aneurysmorrhaphy for the treatment of aneurysm and reported the case in the same year. The *Annals of Surgery* for November, 1940, which is a symposium on aneurysms and vascular surgery, contains a review by Matas of a personal series of 620 operations performed upon the blood vessels for all causes between the years 1888 and 1940, a further article from him on aneurysm of the abdominal aorta at its bifurcation into the common iliac arteries, and contributions from other workers on various aspects of vascular surgery and the treatment of aneurysms. Of Matas's total of 620 operations, 417 were on the common carotid or its branches and 203 at other sites, while 260 were for aneurysm and 360 for other conditions. The different anatomical sites and the operative and technical details are analysed and classified. Suture methods were employed in 101 cases, and ligation, including aluminium bands, in 519. There were only thirty deaths in the series, or a mortality of 4.83%. This detailed record, which concludes with a list of 108 contributions by Matas to the literature of vascular surgery, is a monument to his wide clinical interests, technical skill, and critical and scientific outlook. His work has served and should still serve as an inspiration and encouragement to younger men the world over.

CALCIUM THERAPY IN CARDIAC FAILURE

Lauder Brunton, in 1907, recommended calcium chloride for the treatment of cardiac failure. A synergic action on the heart by calcium and digitalis was demonstrated a few years later by A. J. Clark,¹¹ and O. Loewi¹² advanced the theory that the action of the digitalis depended on sensitizing the heart to calcium ions. During the last twenty years the action of calcium, with or without digitalis, in cardiac failure has been investigated by many authors, but the results have varied widely. There is a fairly general agreement that calcium salts given orally are not effective, but that intravenous injections cause slowing of the heart rate. This method calls for caution because rapid administration may lead to severe toxic manifestations. The introduction of calcium gluconate, however, has greatly facilitated intravenous administration. Rozen¹³ gave this preparation to forty-one patients with varying degrees of cardiac failure, and in most of them there was a notable slowing of the pulse. This was much greater where the rhythm was regular than in cases of auricular fibrillation. The effect is probably due to vagal stimulation, because in ten cases out of fifteen in which atropine was previously given there was no calcium bradycardia. Clinical improvement was noted in fourteen cases, and the author concluded that intravenous cardiac therapy should be adopted for patients with cardiac decompensation who have not responded to digitalis.

At the quarterly meeting of the Council of the Royal College of Surgeons of England on July 10 Sir Alfred Webb-Johnson, C.B.E., D.S.O., was elected President for the ensuing year, in succession to Sir Hugh Lett, Bt.

CHEST SURGERY IN WAR

This is one of a short series of articles based on lectures given at the British Postgraduate Medical School, Hammersmith

SOME ASPECTS OF CLOSED WOUNDS OF THE CHEST*

BY

J. G. SCADDING, M.D.

Major, R.A.M.C.

Suggested Programme of Treatment

Prophylactic chemotherapy should be given as early as possible in every case, on lines similar to those recommended for other war wounds (Fuller and James, 1940). The possibility of prophylactic local application of sulphphonamide drugs to the pleura by injection of suspensions of the drugs in a suitable vehicle seems as yet to be unexplored; local application to wounds elsewhere has been successfully used. Though local application to the pleura in cases of established infection with empyema has been disappointing, the method seems well worthy of trial as a prophylactic against the development of infection.

Immediate surgical treatment is necessary for cases showing the indications already described under "Surgical Intervention." Wherever possible, this and other forms of treatment should be planned after study of radiographic appearances.

In cases with "closed" wounds not showing indications for immediate surgical intervention, and those in which after necessary surgical treatment the chest has been closed (according to the indications outlined above), treatment should be planned to keep the pleura free from blood and exudate by aspiration, and to manage the pneumothorax most advantageously. These questions receive further consideration below.

Surgical intervention on the usual lines is required later for such conditions as empyema, pulmonary abscess, etc.

Management of the Closed Thorax after Penetrating Wounds

In most cases there will be varying amounts of blood and air in the pleura. The advantages of keeping the pleura free from blood and exudate seem overwhelming; the risk of infection, especially by anaerobic organisms, developing in spite of prophylactic chemotherapy is probably much less, and the occurrence of disabling pleural thickening and pulmonary fibrosis by partial organization of the slowly absorbing blood and exudate is avoided. The drawbacks are that unless efficiently performed early aspiration may be exhausting to a shocked patient; that aspiration may be difficult on account of fibrin clot which blocks the needle; and that simple aspiration may result in the recurrence or increase of bleeding by causing re-expansion of the partially collapsed lung. The latter danger may be avoided by air replacement at all early aspirations; this should certainly be done if there is evidence of pulmonary haemorrhage in the form of bright haemoptysis. With these points in mind the following list of indications may be suggested:

(i) *Aspiration and Air Replacement.*—These are indicated in all cases in which within a few days of wounding there is a considerable haemothorax. The indication for air replacement is not so strong if no haemoptysis occurs, but if there is haemoptysis early aspiration should be accompanied by air replacement.

Air replacement is contraindicated if there is evidence of a pleural infection.

(ii) *Simple Aspiration.*—This is required in cases seen later in which there are signs of considerable effusion into the pleura but without haemoptysis, and in cases in which a pneumothorax has been present for several days, haemoptysis has ceased, and there is a reaccumulation of fluid, especially if the temperature and pulse are rising, suggesting incipient infection. In the latter type of case the object of treatment should be to secure re-expansion of the lung to minimize the size of the empyema that may develop.

(iii) *Artificial Pneumothorax.*—The cases considered under heading No. i will be left with an artificial pneumothorax. In a few instances a wound of the lung may be causing haemoptysis without any considerable haemothorax or traumatic pneumothorax. In these, if haemoptysis continues, the formal induction of an artificial pneumothorax may be a very satisfactory line of treatment. In any case, when an artificial pneumothorax is induced by either of these methods it should be maintained for a few days only; possibly no refill, or at most only one, will be required. As soon as active pulmonary haemorrhage has ceased, as shown by the disappearance of bright blood from the sputum, no further refills should be given, and the lung must be allowed to re-expand slowly by spontaneous absorption of the air in the pleura. The value of artificial pneumothorax has been emphasized, on a basis of practical experience, by Kretzschmar (1940).

Technique of Aspiration

A few words about the technique of aspiration of the chest may be useful. Three points require attention: first, the patient must be supported comfortably in a convenient position, both so that he is not exhausted by the effort of

FIG. 2.—A useful position for aspiration of the chest, air replacement, etc.

maintaining it and so that the operator is not incommoded by difficulty of access to the chosen site; secondly, the common error of inserting the needle too low must be avoided; and, thirdly, a needle of adequate bore for the type of fluid present must be used.

Posture.—There may be factors, such as the site of external wounds, which influence decision about the most suitable posture. In most cases, however, that shown in Fig. 2 is possible and is very convenient. The patient sits propped up in a rather upright Fowler's position; with the arm of the sound side he clasps a blanket or blankets rolled into a cylinder about sixteen inches to eighteen inches

* Concluded from p. 58.

long, while the arm of the affected side is placed so that the hand rests on the opposite shoulder and the elbow rests on the top of the rolled-up blanket. This posture leaves the whole of the lateral wall of the chest accessible to the operator sitting by the bedside. It can be maintained without distress even by an ill patient.

Insertion of Needle.—In most cases of effusions into a free pleura the needle should be inserted in the fifth or sixth intercostal space in the mid-axillary line with the patient in the position described. The disadvantage of inserting the needle lower than this is that it is apt to get intermittently blocked by the diaphragm at the height of its excursion, that fibrinous particles are more numerous in the costo-phrenic "gutter," and that this "gutter" is in any case more narrow in its lower part, so that it may easily be almost obliterated by fibrinous deposit on the pleura. These troubles are minimized by inserting the needle higher up; if this has been done the last part of the fluid may be withdrawn by leaning the patient over towards the affected side.

Size of Needle.—The importance of using a needle of adequate bore seems too obvious to require emphasis. There is one difficulty, however—namely, that most large-bore needles are made much longer than necessary for pleural aspiration. Those supplied with most of Potain's aspirator sets are an example of this. Very few chest walls require a needle more than two inches in length; and unnecessary length partly defeats the purpose of a wide-bore needle by increasing the resistance to flow. Aspiration of a haemothorax may prove very difficult on account of repeated blockage of a needle of the usual sort, even of wide bore. In such cases it is tentatively suggested that larger trocars and cannulae, such as are used for the insertion of intercostal catheters or for thoracoscopy, might be tried. A trocar and cannula of this size can be inserted painlessly if the technique is sufficiently careful. The chosen site must be adequately anaesthetized, 20 c.cm. of local anaesthetic solution being required; the presence of fluid is confirmed; a small incision is then made with a fine scalpel or tenotomy knife, and through this the trocar and cannula are steadily thrust between the ribs into the pleural space. Aspiration through such a large cannula, if thoroughly performed, would rarely need to be repeated. It might be advisable to irrigate the pleura with normal saline at the end of such an aspiration to ensure that no fibrinous debris is left to interfere with subsequent aspiration through a more normal needle, should it prove necessary. During this procedure the interpleural pressure should be controlled by introducing or removing air through a second needle inserted higher up, as described below under "air replacement." After withdrawal of the trocar the small wound should be closed by a single stitch, and a dressing, firmly supported by elastic plaster, applied.

Technique of Air Replacement

Air replacement requires, in addition to aspirating apparatus, devices for measuring the intrapleural pressure and for admitting air, preferably in measured volume, into the pleura. These are, of course, both provided by any form of apparatus used for artificial pneumothorax work. Preparations having been made for aspiration as outlined above, a second needle is introduced, in the manner described for measuring the intrapleural pressure, higher up above the level of the fluid. Through this, as the fluid is withdrawn through the lower needle, air is admitted at such a rate that the intrapleural pressure is kept as constantly as possible at the desired level. The pressure required in the individual case can be judged from the degree of lung collapse initially present and the initial pressure before aspiration is begun. In general, in order to main-

tain constant pressure within the pleura rather less volume of air must be introduced than fluid withdrawn. The pressure required to produce a useful degree of lung collapse varies greatly: it will always be below atmospheric in patients with previously healthy lungs—generally the mean pressure will lie between 0 and -4.

If a pneumothorax apparatus is not available the pressure may be measured with the manometer described on page 57, and the aspiration stopped occasionally to allow time to be injected through the lower (aspirating) needle with a large syringe, the amount being controlled by observation of the intrapleural pressure. This is a safe procedure, provided it is certain from the free flow of fluid on aspiration that the needle is in the fluid-containing space.

If there is a large haemothorax with no considerable space above it, and an air replacement is indicated, the easiest procedure is to start as for simple aspiration. Withdraw about 100 c.cm. of fluid has been withdrawn inject 80 c.c. of air through the aspirating needle, and continue thus until a useful air space is present above the fluid. Insert the upper needle into this, and proceed as in the cases with initial air space.

Infection.—This complication should be watched throughout. So long as fluid accumulates in the pleural space specimens must at intervals be examined bacteriologically by both aerobic and anaerobic culture, especially if the temperature rises or fails to fall. It is to be hoped that the incidence of infection will be reduced to a very low level by prophylactic chemotherapy and thorough early aspiration. When it occurs the case must be treated in accordance with the general principles of the treatment of pleural infection which cannot be discussed here. It may be stressed that so long as there is a pyothorax—i.e., a collection of purulent fluid in a free pleura—aspiration or drainage by the most efficiently closed method must be used; only when the condition has settled into a localized walled-off empyema may an open method of drainage be employed.

Tension Pneumothorax

This is a rare complication of chest wounds; it results from a pleuro-bronchial communication of valvular type, so that air can enter the pleura in inspiration and cannot leave it during expiration. The pleura thus becomes distended by air under pressure, causing gross mediastinal displacement and dangerous respiratory distress.

The presence of a tension pneumothorax may be suspected when there is extreme respiratory embarrassment with cyanosis, and on examination the affected side of the chest is immobile, possibly distended, hyperresonant on percussion and either silent or (rarely) with curious amphoric respiratory sounds on auscultation, and the heart and possibly the trachea are displaced on the opposite side. The diagnosis is made precise by measurement of the intrapleural pressure, which will be above atmospheric.

Such a case calls for immediate measures for its relief. In emergency, with no apparatus to hand, relief may be obtained by simply thrusting a needle into the pleura through one of the upper intercostal spaces. The outward hiss of air is easily audible if a tension pneumothorax is present, and confirms the diagnosis. This simple insertion of a needle brings the intrapleural pressure to atmospheric and results in considerable relief of urgent symptoms. If the apparatus is available more information about the site of the valvular opening may be obtained by measuring the pressure, withdrawing a measured volume of the pleural gas to reduce the pressure a little below atmospheric, and watching for a time to see whether the pressure rises again. If it does not the needle may be withdrawn and the patient watched for recurrence of distress. If the pressure mounts rapidly or, after the needle has been withdrawn, distress

recurs rapidly, a suitable needle may be inserted and connected to a rubber tube attached to a simple under-water drainage bottle as used for closed drainage of empyemata (Fig. 3). This will afford great relief, but has the disadvan-

FIG. 3.—Simple under-water drainage bottle.

tage that, as air is expelled during cough, it may result in the development of a low intrapleural pressure, with too rapid re-expansion of the lung, giving the pleuro-bronchial fistula no chance to heal. It may be more satisfactory, in a patient who is not distressed by an intrapleural pressure equal to atmospheric, to leave a needle *in situ* open to the air, preferably through a loose cotton-wool filter. If, however, the patient is distressed with an atmospheric intrapleural pressure the arrangement shown in Fig. 4 may be

FIG. 4.—Apparatus for under-water drainage of tension pneumothorax, with safety-valve.

used. In this, bottle B is added to the simple under-water drainage bottle A to act as a safety-valve, letting air into the system whenever the pressure gets below a level equal to that number of centimetres of water below atmospheric by which the tube C projects below the surface of the water in bottle B. This is of course adjustable to whatever level is required for relief of the patient's discomfort. The other more complicated apparatus described by Marriott and Foster-Carter (1940) may be used for the same purpose.

In general, in the treatment of valvular pneumothorax as little air as possible should be withdrawn or the pressure maintained as near atmospheric as it can be, in order to keep the lung as firmly collapsed as is consistent with the patient's comfort, since only thus has the pleuro-bronchial opening the best chance of healing. In valvular pneumothorax due to wounds surgical intervention will often be indicated; but the measures outlined above may be necessary life-saving preliminary steps.

HEALTH INDICES FOR GREATER LONDON AND NEW YORK, 1931-40

BY

PERCY STOCKS, M.D., F.S.S.

Medical Statistician, General Register Office, London

In a leading article (*Journal*, February 8, p. 201) dealing with the provisional notification and death rates from certain causes in the city of New York for the year 1940 regret was expressed that no recent death rates were available for London with which these could be compared. The February issue of the Quarterly Bulletin of the Health Department of New York City contained the death rates in each year from 1931 to 1940, at appropriate ages, from diphtheria, scarlet fever, measles, whooping-cough, tuberculosis, pneumonia, appendicitis, suicide, homicide, accidents, and some other causes. Greater London and New York are at present not far apart in their total populations, and it is of interest from a public health standpoint to compare the changes which have occurred in the death rates from these causes in the two cities since 1931. In such a comparison it must be remembered that while the New York figures do not include deaths of residents which occurred outside the city and do not exclude those of non-residents which occurred within the city, the Greater London rates have been corrected for inward and outward transfers and represent the total mortality suffered by residents. The effect of this can be illustrated from the following example. In 1940, 227 deaths from diphtheria, scarlet fever, measles, and whooping-cough were registered in Greater London, but of these only 104 were of residents; in addition 163 deaths of Greater London residents from these causes were registered in other administrative areas of England and Wales, making a total of 267 residents, compared with 227 registrations. If the same conditions hold for New York this would account for an apparent excess of 18% in the combined rate for these diseases in Greater London, but if a larger proportion of New York's infectious disease hospitals lie outside the city's boundaries a still greater apparent excess might result. The same considerations apply to tuberculosis, from which cause a large proportion of deaths of town dwellers occur in institutions situated in the country, and unless these are transferred to the towns of residence the death rates of the latter are fictitiously low. In New York it has been ascertained that the addition of deaths from tuberculosis of residents occurring outside the city would increase the rates by about 10%. Causes such as pneumonia and appendicitis are not likely to be affected to the same extent, but the general death rate of Greater London is raised appreciably by the process of allocation of all deaths to the place of residence of the deceased. In the December quarter of 1939, for example, 19,309 deaths from all causes were registered in the area, 6,360 of these being of non-residents, while 7,512 residents died elsewhere; the corrected death rate was consequently 6% in excess of the uncorrected rate.

Since it is uncertain to what extent the New York death rates are understated owing to this absence of correction, the best method of comparing the progress made in the two cities since 1931 is to study the changes in the ratio of the Greater London death rate to that of New York. Changes since 1931 in the distribution of hospital cases in and around New York are unlikely to have seriously affected the ratio, and if it has consistently increased the conclusion may be drawn that progress in reducing mortality from the disease in question in Greater London has not kept pace with that in New York, and vice versa.

For diphtheria the London/New York ratio in 1931-4 ranged from 2.0 to 6.5, but in 1937-40 it ranged from 6.0 to 8.6, for whilst New York has reduced the toll of this disease by more than 85% since 1932, Greater London's rate has fallen by little more than half. For scarlet fever, however, the ratio has not changed consistently, the average death rate in Greater London having fallen from 66 in 1931-4 to 15 in 1937-40 and in New York from 49 to 12—that is to say, by more than 75% in each city.

Diphtheria and Scarlet Fever. Death Rates per Million Children Under 15 Years of Age

1940	121*	14	8.6	7	9	0.8

* Provisional rates.

For measles the annual London/New York ratio has fluctuated greatly owing to epidemics occurring in different years, but when the average rates in 1931-4 and 1937-40 are compared it is evident that a parallel decline in mortality of children under 5 has occurred in the two cities, the London rate remaining at 5 times that of New York. For whooping-cough a slight fall has taken place in the ratio in recent years.

Measles and Whooping-cough. Death Rates per Million Children Under 5 Years of Age

Year	Measles			Whooping-cough		
	Gr. London	New York	Ratio*	Gr. London	New York	Ratio*

1940	132	7	19.0	70	108	0.6

* Ratio of average annual rates - Provisional.

Greater London's tuberculosis death rate in 1931 was 1.27 times that recorded for New York, but as it is estimated that the latter would be increased 10% by inclusion of deaths of New York residents occurring away from the city, the real excess in the crude death rate must have been about 15%. The ratio declined from 1.28 in 1933 to 1.10 in 1936, indicating a more rapid improvement in London in that period and bringing the crude death rate to equality with that of New York. Since 1936, however, the ratio has risen again year by year to 1.23 in 1939, this being due to an accelerated decline in New York in recent years combined with a setback in London in 1939.

Tuberculosis and Pneumonia. Death Rates per Million Persons of All Ages

Year	Tuberculosis (All Forms)			Pneumonia		
	Gr. London	New York	Ratio	Gr. London	New York	Ratio
1931	893	704	1.27	881	1,323	0.67
1932	825	645	1.28	747	1,113	0.67
1933	831	647	1.28	725	1,056	0.68
1934	776	621	1.25	728	948	0.77
1935	706	610	1.15	591	891	0.66
1936	702	636	1.10	709	903	0.78
1937	684	588	1.16	740	896	0.83
1938	626	525	1.19	630	649	0.97
1939	640	520	1.23	555	576	0.96

New York's pneumonia death rate was much above that of Greater London during 1931-5, but in the short period 1936-8 the excess was reduced until approximate equality was attained in 1938 and 1939. There can be little doubt that this achievement may be credited to the great efforts made in the United States to combat pneumonia by serum therapy, and that the parallel decline noticeable in both cities since 1938 reflects the application of the new discoveries in chemotherapy.

Another cause from which New York has for long recorded a much higher death rate than London is appendicitis, but, as in the case of pneumonia, the rate of improvement since 1931 has been more rapid in the former city, with a resulting increase in the ratio between the average annual death rates from 0.47 in 1931-3 to 0.55 in 1934-6 and 0.57 in 1937-9.

Appendicitis. Death Rates per Million Persons of All Ages

Year	Gr. London			Ratio	Year	New York		
	Gr. London	New York	Ratio			Gr. London	New York	Ratio
1931	75	166	0.45		1936	72	145	
1932	74	151	0.49		1937	72	129	
1933	75	162	0.46		1938	68	113	
1934	78	141	0.55		1939	60	109	
1935	80	128	0.63					

The suicide rate (which in Greater London is not appreciably affected by allocation of deaths to the place of residence) was high in both cities during the years of economic depression, but since 1934 there has been little change. London rate being about four-fifths of that in New York. For other violent deaths the ratio has tended to increase. Greater London's death rate being 54% of that in New York in the years 1931-2, rising to 68% by 1939. Correction of this death rate by allocation to place of residence brings about an increase of 6% in Greater London, and the same is true of New York the corrected ratios will be 6% less than the figures tabulated.

Suicides and Other Violent Deaths per Million Persons of All Ages

Year	Suicide			Other Violence		
	Gr. London	New York	Ratio	Gr. London	New York	Ratio
1931	135	215	0.63	401	747	0.54
1932	154	227	0.68	376	690	0.54
1933	154	190	0.81	406	675	0.60

1938	134	171	0.78	350	566	0.62
1939	124	162	0.77	390	573	0.68

Turning finally to infant mortality rates from all causes, 22,934 deaths of infants under 1 year of age occurred in New York City in the period 1934-8, and when all deaths in New York State had been allocated to the place of residence the number was 22,744, or 1.7% less. But were affected to a similar extent, however (504,436 be reduced to 497,504, or by 1.4%), and the infant mortality based on live births may be regarded as free from substantial error and comparable with those of Greater London. The increase in the ratio since 1935 shows that London has not kept pace with New York in its reduction in infant mortality, for whereas Greater London

Infant Mortality per 1,000 Live Births

* Provisional estimate.

average rate in 1931-3 was 8% above that of New York, the excess was 13% in 1934-6 and 24% in 1937-9. War conditions must inevitably further retard improvement in London rate and increase the widening gap for the time being, but when the reconstruction period is reached careful consideration will need to be given to the reasons why New York began to draw ahead about 1936 in this important matter of infant survival, notwithstanding a more difficult climatic and racial background. The average annual death rates per 1,000 live births in the five years 1932-6 from some of the important causes are compared below.

	Greater London	New York
Prematurity	13.2	13.2

All causes under 1 year	53.7	45.6
.. .. . under 1 month	23.1	28.1
.. .. . 1-12 months	29.6	17.5

* Births, Stillbirths, Maternal Mortality, and Infant Mortality in New York State, 1934-8. State Department of Health, 1940.

Greater London's post-natal death rate compares favourably with New York, the excess being amongst infants between 1 month and 1 year of age, and towards the total excess of 8 per 1,000 live births diarrhoea and enteritis contribute one-half and pneumonia and bronchitis about one-fifth. Infantile diarrhoea is sometimes regarded as a subjugated disease which has ceased to be an important cause of death, but it is well to realize that 8 or 9 infants out of each 1,000 born are still being certified as dying from this cause in London. Small though this may appear in comparison with figures of thirty years ago, the time for complacent self-congratulation on past achievements in public health has surely come to an end, and the point to be considered is why that which is being achieved now in New York cannot be also achieved in London. A keen rivalry between cities in the matter of their health indices, particularly for infants and children, comparable to what we have witnessed in the financial and other phases of our war efforts, should be our aim in the future, and in the case of Greater London, with its complex administration, this will entail team-work if New York's health record is to be overtaken in the post-war period:

HOSPITALS AND AIR RAIDS

ORGANIZATION OF A CITY CASUALTY HOSPITAL

It is the aim of our wartime medical services, albeit in the face of new, varying, and often difficult conditions, to provide with as little delay as possible the best possible initial treatment and to secure the fullest possible restoration to health and efficiency for each individual casualty. Stresses and numbers may sometimes necessitate, but must not become an excuse for, lower standards. Planning in advance can achieve much, but plans must be elastic and susceptible of quick change. Mistakes must be freely admitted and experiences constantly shared. Those severally responsible for the collection, transport, and treatment of wounded should have a proper understanding of each other's tasks and difficulties. More intensive aerial bombardment may yet await us.

In these notes the organization of a city hospital for the reception, treatment, and evacuation of casualties and associated duties are briefly reviewed. The notes are based on experience gained at a London teaching hospital working as a casualty clearing station and possessed, therefore, of the advantages of an ample student personnel for the provision of dressers, clerks, stretcher-bearers, runners, etc. The assistance which students have given can scarcely be overstressed. It is fully appreciated that, with their different constitution and prevailing shortage of male civilian personnel, other types of hospital must needs employ alternative measures. The suggestions outlined, however, with local variations, should be generally applicable to most large city hospitals equipped for the direct admission of casualties on a large scale.

It is well worth considering application to local Scout organizations for the night-time services, in return for supper and breakfast, of squads of Rover Scouts to assist with such duties as those of stretcher-bearer, tally clerk (for stretchers and blankets), or runner. For help as well as training the presence of St. John Ambulance men can also be arranged. As many wheel-trolleys as possible should be accumulated to lighten the work of the bearers.

In hospitals serving cities already bombed or liable to be bombed provision must be made for: (1) reception of cases from the ambulance; (2) preliminary inspection of injuries in the receiving room followed by administration of A.T.S. (unless it be decided to make a routine of giving it in the theatre when the patient is under the anaesthetic), the sorting of cases into categories according to severity, and the recording of particulars; (3) resuscitation; (4) operation; (5) subsequent treatment; (6) evacuation to a "base" hospital; and (7) mortuary identification and disposal.

Ideally the personnel required on duty at night during a raid in a hospital capable of receiving up to or over 100 casualties

should include: (1) a Medical Officer in Charge of staff rank; (2) a senior member of the surgical staff to supervise the surgical decisions of the resuscitation ward, the theatre, and the surgical wards generally; (3) operating surgeons sufficient for the available tables, say from three to five, preferably men of the standing of surgical registrar and sometimes including members of the general or specialist surgical staff; (4) a staff physician in charge of the resuscitation ward and for consultation with the surgeon in cases of wound shock or of chest or neurological injuries; (5) a receiving-room officer—either a member of the specialist staff or an experienced senior house-surgeon; (6) anaesthetists, of whom one should, if possible, be of staff and one of junior staff rank; (7) a radiologist or experienced radiographer; (8) house officers; (9) matron, sisters, nurses, and almoners; (10) engineering and domestic staff, porters, stretcher-bearers, and fire-watchers.

Duties of Senior Officers

1. The Medical Officer in Charge has numerous functions to perform during an air raid. He should be assisted by a responsible secretary or telephonist and a runner: the first of these at his office or night control room, the second either at the control room and kept informed as to his moves or accompanying him on his rounds. He must keep an eye on the number and rate of admissions, and when the hospital's capacity from the point of view of efficient surgery is nearing saturation must make contact by telephone (when possible) with Controls or through the local police with the ambulance service, or with a neighbouring hospital, stating his desire to divert convoys. In practice direct communication in any case with the neighbouring hospital is valuable in order to maintain a friendly reciprocity and to discover how far its staff may be working under stress or able and willing to receive. If other means of communication fail messages should be sent by a returning ambulance. He must tour the wards frequently during the raid to see that all is well and to reassure and encourage nursing staff and patients. It may be necessary for him to visit other parts of the institution or to look into some reported incident or difficulty. He may have to order the evacuation of a ward which has sustained damage or had its windows blasted, or call up extra personnel to deal with incendiary bombs, or summon the fire brigade. He must keep in touch with the matron and with the hospital engineer, who is one of his most valuable lieutenants and under whose direction the fire-watchers and their reliefs should usually be disposed. He must see that operating surgeons and theatre and resuscitation ward staff are relieved without undue delay after an all-night session. He must consult with the surgical officer in charge on matters of policy, and particularly in regard to the pressure of work and the evacuation of casualties on the following day.

2. The surgical O.C. visits the resuscitation ward (which should be a separate unit but as conveniently situated as possible for both the theatre and other casualty receiving wards) as soon as it begins to fill. He should there keep the personnel to a reasonable minimum to avoid congestion and the "too many cooks" tendency. When the first admissions have been attended to and have begun to benefit from the rest and warmth he should make a systematic tour of inspection, dictating a statement of the injuries in each case, ordering in consultation with the physician-in-charge (who remains in the ward) a transfusion here, a dressing or a dose of morphine there, marking up cases for examination with the portable x-ray plant, and entering against the names of the operating surgeons on a conveniently placed blackboard at the entry to the ward the bed-numbers of the cases selected for them in order of need and paying due regard also to the skill and experience of the individual surgeons. He has the same functions to perform in respect of the ward or wards to which the less severe cases are admitted and from which cases are drawn for the theatre pending the resuscitation of the more severe. The graver cases may be conveniently returned after operation to the resuscitation ward to ensure continuity of treatment. He may at intervals give advice in the theatre, and when admissions are few or his other tasks are done he may elect to take a table himself for a selected case or cases. Operating should never, however, be considered his prime function. On the morning following a raid he should help his operating colleagues and their house-surgeons with the selection of cases for immediate evacuation, and he may here need to be guided

by the situation and "bed state" as put to him by the medical officer in charge. It is most important for him to establish communication with surgeons responsible for special lesions in special centres with regard to consultations on or transfer of cases of neurological, thoracic, or facio-maxillary injury.

3. The physician in charge of the resuscitation ward has a special responsibility on the spot for all the more serious cases and (with a transfusion officer or experienced resident to help him) for the transfusion of blood, plasma, or other fluids, or the withholding of these. He directs the sister in charge of the ward in the matter of fluids to be given by mouth or rectum, the administration of oxygen, and the undressing or movement of patients—decisions of considerable moment with the badly shocked cases. He should supervise the keeping of records with full notes of pulse, blood pressure, haemoglobin estimations, vomiting, blood loss, etc., in all grave cases, and should assist his surgical colleague with the difficult decisions as to the optimum time for operation—decisions which his closer and more continuous contacts will materially assist. When the admissions are few he should take the opportunity of making detailed continuous observations on a selected case or cases with a view to increasing his own and the general body of information on the varied manifestations composing the picture of traumatic shock and to advancing treatment. In this work valuable guidance may be obtained from the Shock Committee of the Medical Research Council. His judgment should be sought in the case of thoracic wounds and cranial or other neurological injuries. It has not been found necessary to arrange for separation of the sexes in the resuscitation ward; uniformity of administration and treatment and valuable economy in time and skilled personnel can thus be secured.

4. The receiving-room officer, who should be assisted by a sister and nurses and where available by a junior house officer or by students, and also by the almoner's clerical staff and a sufficiency of stretcher-bearers, should make only a very superficial examination of the casualties, his aim being to decide whether they should be admitted to the resuscitation or casualty ward in the case of stretcher casualties, or to a casualty ward or rest room for discharge in the morning in the case of the walking wounded. At this stage it is quite impossible to form any considered judgment of extent of wounding, operability, etc. Approximately ten minutes per ambulance load of four stretcher cases for his inspection and decision, for the administration of A.T.S. (if given at this stage), and for the taking of particulars should suffice once his team is trained. He may judge that a case is too bad for any of these formalities and pass it direct to the resuscitation ward; in this event it is the duty of the almoner's clerical staff to follow and secure the particulars later. He should err in the direction of sending lighter cases for resuscitation rather than in that of burdening the other wards with serious cases. Among the admissions will be many not requiring operation—concussions, severe bruising, fractured ribs, simple fractures, etc. It has been found that about 50% of all admissions require operation. Upwards of 25% of all admissions may require resuscitation. A resuscitation ward in a hospital equipped for 100 or more casualties should, therefore, when possible, accommodate between twenty and thirty patients and include a side room for necessary equipment.

Radiography

Out of consideration for the patients, and to lighten the task of the stretcher-bearers and preserve quiet and diminish traffic in wards and passages, radiography by night should be carried out with the portable apparatus. Casualties requiring a fuller examination will generally be in a fitter state for this on the following day.

Identification and Other Mortuary Duties

Unless the mortuary is conveniently situated and commodious, separate accommodation must be set aside for persons brought in dead or dying during the night. With an admission of 100 there may be from ten to twenty persons dead on arrival or dying soon afterwards. A most unpleasant but very important duty is that of cleaning up these pitiful victims to make them presentable for those who come to identify them later in the night or in the morning, of carefully collecting and making an inventory of their belongings and placing them in a bag, of

discovering identity cards, which are commonly lacking (the general use of identity disks is much to be desired), and of searching for physical marks or other evidences which may assist what is sometimes a very difficult task of recognition. At one teaching hospital student volunteers have been found to carry out these duties while a kindly and tactful sister and a medical officer of junior staff rank interview relatives. The usual mortuary assistant should report as early as possible on the morning after the raid to arrange the bodies which have received initial attention during the night, to assure the cleanliness of the viewing room, and to give other assistance pending removal of the bodies to the public mortuary or elsewhere. A proper liaison should be established with the local authority to ensure the removal of bodies to the public mortuary within twenty-four hours. Trestles and a supply of old stretchers should be kept in the mortuary in order to free the standard stretchers for cleansing and further use in the hospital. When permission can be obtained, it is of real importance for the advancement of knowledge to carry out post-mortem examinations in certain types of injury. Up to date various difficulties and delays have tended to thwart such inquiries.

Evacuation

When casualties have been numerous during the night as complete an evacuation as possible will be necessary on the morrow to clear the wards for further admissions. The medical officer in charge will have obtained directions from his Hospital or Group Officer as to the destinations of casualties, including those requiring transfer to special centres. A house-physician or other house officer who has not been actively engaged during the night should superintend the loading of ambulances and hand over the lists and notes to the nurses allocated by the matron to accompany them. It will rarely be possible to start the evacuation before 2 p.m., by which time the night surgical and other staff should have retired to rest. One of the most difficult things to cater for is the filling in of the E.M.S. forms and the duplication of the fuller and permanent clinical notes for retention by the hospital and transfer to the "base" respectively. For the comfort of the more serious cases in transit to the "base" many layers of blankets are necessary to serve as mattresses. Where money or gifts are forthcoming there can be no better benefaction than a set of one dozen "sorbo" mattresses with washable covers to fit the standard metal stretchers. These must be checked and sent back with the ambulance conveying nurses and equipment on the return journey.

Reliefs

Relief surgical teams, when not available from a visiting staff, should come from peripheral hospitals. They should work to a rota. After a raid the teams "on call" should communicate with or be warned by the Hospital or Group Officer. If, however, all communications have broken down they should proceed to the hospital which they serve without instructions. The night teams should stop working as soon as possible after 8 a.m. and the reliefs be ready for action by 10 a.m. When arrangements for the diversion of ambulances have been satisfactory it has been rare for the admissions to one hospital to be so numerous that the necessary theatre work could not be finished by midday or early afternoon following a night raid.

As the honorary staff in the case of the voluntary hospitals have many other calls upon their time a rota should be arranged for night duties by the surgeons, physicians, and anaesthetists or others available. At least one surgeon, one physician, and one anaesthetist should be on duty in the hospital during a raid. This is necessary, since it is unfair, when they live at a distance, to summon them during the raid. Furthermore, communications may break down and the approaches to the hospital become difficult. When, however, they live close to the hospital it should be reasonable for them to regard an alert as the indication to go on duty. No large city hospital in a danger zone and lacking a medical superintendent should be without the services of one member at least of the senior staff during the night hours.

Discipline and Other Matters

Practices and lectures should be arranged at intervals for stretcher-bearers, the decontamination and gas treatment units (male and female), and fire-watchers. In the long winter evenings a weekly lecture on general topics, concerts, and debates

make a useful contribution to the maintenance of a good morale and good feeling, and serve to bring together as one family the workers in the many departments, which otherwise carry on from day to day almost in ignorance of each other's functions. Pride in the institution as a unit and in its efficiency is as important for the successful working of a civilian war hospital as it is for a battalion in the field. The medical superintendent and hospital engineer must ensure that there are sufficient sandbags and buckets at all strategic points and that hoses are in order and extinguishers are regularly inspected.

A canteen, running all night and preferably situated close to the receiving room, plays an important part during a raid as a place of meeting and for physical and mental refreshment for internal staff, roof watchers, stretcher-bearers, ambulance drivers, and sometimes for police or firemen working in or near the hospital. If operating has started in the earlier part of the night the whole theatre staff should have at least half an hour off for refreshment between midnight and 3 a.m. It may be necessary for the Medical Officer in Charge to insist on this when the list is long and the surgeons are eager and insufficiently alive to the effects of "industrial fatigue."

In spite of frequent damage by bombs or fire the majority of the large hospitals in London and the other cities affected have thus far been able to carry on their work as casualty clearing stations without serious interruption to their essential work. Certain lessons have, however, been learned. The windows of all important offices and services should be bricked up; these should include the night operating theatres, receiving room, resuscitation ward, and connecting passages. The blasting of windows, apart from the dangers of broken glass, immediately cripples or altogether prevents work owing to the claims of the black-out and the ingress of cold air in winter-time. The theatre in use by night should not be above the ground floor, and wherever possible the same rule should apply to the resuscitation and other casualty wards. Reserve water supplies and lighting should be provided for, and, since gas is especially liable to fail, reserve heating in the form of primus or oil stoves is also necessary. All the alternative routes of exit from wards and the hospital should be in good order and carefully studied by the Medical Officer in Charge and should be known to sisters, house officers, and stretcher-bearers. Plans of evacuation from each occupied ward should be arranged and practised.

Correspondence

Chronic Sick

SIR.—The problem of caring for the "chronic sick" during this war is both a real and an urgent one, and all who have the welfare of sick people at heart must feel compassion for these unfortunates. The solution of the problem is, however, not made any easier by suggestions that the Ministry of Health has not made any attempt to solve it, and that the fact of its existence shows a lack of humanitarianism. A short survey of the position as it affects the Midlands may explain some of the difficulties of the present situation and show that attempts have in fact been made to cope with them.

The number of chronic sick requiring hospital attention in large industrial areas which have been bombed has increased, and is likely still further to increase, because: (1) the destruction of houses has reduced the accommodation available for the chronic sick in their own homes; (2) patients have had to be admitted to hospital because the increased demand for female labour has removed those who would have cared for them in their own homes; (3) the lack of shelter accommodation at the home of the sick person. For these reasons patients who normally would be sent home for convalescence have to stay in hospital; furthermore, the hospital treating these chronic sick may itself have to be evacuated because it has suffered damage or because it is situated in a target area. This problem, therefore, is already an urgent one in some large towns in this area, but it has been made even more acute by the reception of considerable numbers of chronic sick from London and other areas. Sir Frederick Menzies, in his last letter (July 5, p. 31), states

that the number of chronic sick in London is 5,000. I do not know the actual number of chronic sick in London when evacuation started, but judging from the number received in this region, and knowing that certain other regions shared our experience, it seems probable that the greater proportion of London's chronic sick have already been evacuated.

A recent letter in the *Journal* by "De Senectute" (June 28, p. 987) suggested that these patients should be accommodated in rural areas and in those country houses which have been taken over by the British Red Cross, but that they must not be sent to "institutions where the stigma of 'workhouse' still prevails," which, I presume, means the Public Assistance Institutions. The only hospitals situated in quiet rural areas are: voluntary hospitals in small towns which for this purpose can be regarded as rural areas; Public Assistance Institutions; "upgraded" Public Assistance Institutions, with or without additional huts; mental hospitals taken over by the E.M.S.; the auxiliary hospitals of the Joint War Organization of the British Red Cross and Order of St. John of Jerusalem. The small towns are in many instances reception areas, and the strain on their hospital beds has been increased by the presence of official and voluntary evacuees. For instance, one such town which has a peacetime population of 40,000—estimated now to have increased to 70,000—is served by a Public Assistance Institution and a voluntary hospital. In normal times the hospital accommodation can perhaps be regarded as adequate, but to-day, owing to the increase in population, an influx of chronic sick, and of patients from casualty clearing hospitals in other towns, there are only twenty-six empty beds in the two hospitals. While it is true that the voluntary hospital could, by erecting beds in corridors, etc., increase this number by sixty-four, it is clear that there is not even an adequate reserve for calls which may come from the town itself, and that it is quite impossible to accept further chronic sick from London or other large industrial towns.

I gather that "De Senectute" would not allow the chronic sick from large towns to be treated in Public Assistance Institutions, which, however, treat the chronic sick from their own districts, and therefore should surely be able to treat those from other districts. It is true that some of the smaller and older of these institutions leave much to be desired, but many of those which have been "upgraded" are first class in every way, and will bear comparison with voluntary hospitals. Indeed, except for those special facilities for investigation which are usually found only in teaching hospitals, it would be difficult to improve upon them. These, with a few mental hospitals which have been taken over by the E.M.S., are the only general hospitals to be found in truly rural districts. It is true that the auxiliary hospitals have never been used to anything like capacity, many indeed having only a few beds occupied and a staff which is intensely bored and discouraged by a long wait for patients. The Joint War Organization does not, however, allow them to be used for chronic sick, and, as a matter of fact, if in this region every bed were occupied by a "chronic sick" patient it would be impossible to accommodate in them all the chronic sick who have been received into the region. In my opinion the Organization would still further help the medical services of this country if they would relax their regulations, but they can plead at least three good reasons why they should not do so:

(1) Auxiliary hospitals are only equipped to deal with convalescent patients whose lengths of stay, without reference back to the parent hospital, is limited to three weeks.

(2) These hospitals are by way of an insurance providing a reserve of beds into which Service patients and civilian casualties can be emptied if a large number of casualties have suddenly to be catered for.

(3) There is a small minority of chronic sick whose behaviour is reprehensible.

Another difficulty in the present situation is that in many instances the chronic sick are occupying beds provided for acute and Service sick and air-raid casualties. As a result there may be inadequate accommodation for those whose immediate need may be even greater than that of the chronic sick. According to "De Senectute" humanitarianism demands evacuation of the chronic sick from the large towns, and the "thousands of beds" thus set free would be invaluable for air-raid casualties, but if it is too dangerous to treat chronic sick in large towns, it could

surely be argued that air-raid casualties should also be treated elsewhere. It seems clear, therefore, that further accommodation must be sought for the chronic sick, and I believe that in some districts large houses, etc., have been set apart for this purpose. I have tried to obtain houses in rural areas in the Midlands for this purpose, but so far without success. There is a great opportunity for the philanthropically minded owners of large houses to offer them for this purpose, although a sufficient number may not be available because so many large houses and institutions are earmarked by one of the various Ministries.

The nursing of the chronic sick also presents problems which should be faced. Many members of the C.N.R., Red Cross, and Order of St. John joined these organizations to nurse soldiers and air-raid casualties, and protest loudly at being called upon to nurse chronic sick. They find the work uninteresting, complain bitterly of the behaviour of some of their patients, and some have resigned. Surprise has been expressed that nurses should resign for these reasons, but when it is remembered that many of them are young girls experiencing their first contacts with rather sordid conditions, and that some of the patients, possibly as a result of senile mental changes, use foul language and have been known to throw their dinner at them or on the floor, it is, perhaps, understandable that some feel they cannot face the conditions. In this connexion it should also be remembered that if these patients wilfully disobey instructions they cannot be dealt with as an ordinary voluntary hospital patient and sent home. In more than one instance a disgruntled patient, particularly if he has been evacuated from a distance, has written to his Member of Parliament complaining about the food and treatment he has received, and a question, perhaps couched in indignant terms, has been asked in the House. Machinery is thus set in motion which results in a medical officer of the Ministry of Health having to visit the hospital and inquire into the complaint. In a typical case, which involved 140 miles of motor travel and the greater part of a busy medical officer's day, the report eventually appeared in the daily Press and contained the following sentences: "I spoke to many of the patients, and all expressed themselves satisfied with their treatment. The master and the matron and all the staff have done everything possible to make everybody comfortable. . . . In my opinion this group of sick and infirm patients from London has been treated very efficiently, both medically and otherwise."

It should be stated quite clearly that these displays of bad behaviour and complaints only come from a very small section of the patients, the great majority being extremely grateful for the care taken of them. I cannot say that all complaints are as groundless as the one mentioned above, but I can say that it is only rarely that a complaint is justified; indeed, these patients are looked after in a way which reflects the greatest credit on the nursing, medical, and administrative staff of the local authorities. I would like to bear testimony to the generous way in which the staff of one particular emergency hospital in the northern part of this region has responded to every call made upon them to receive chronic sick from many places in the Midlands and still further afield. I do not believe that this hospital has received a single acute case since it has been an E.M.S. hospital, but it has earned the gratitude of the many chronic sick who have been treated within its precincts and of those who have to administer the Emergency Medical Service in this region.—I am, etc.,

Birmingham, July 7.

LEONARD G. PARSONS.

Protecting Eye-shields

SIR.—In the *Journal* of June 14 (p. 914) I read: "Captain Margesson, replying to Mr. Purbrick on June 10, said that at the request of the War Office the question of affording additional protection against eye injuries in the Army had been very carefully examined by an expert committee of the Medical Research Council in the light of evidence provided by this war and the last. Several tests of various kinds of protective devices had been carried out. As a result, the committee had now recommended that *no special vizor in any material was required other than the present anti-gas eye-shield.*" (My italics.) At the Congress of the Ophthalmological Society of the United Kingdom held in April, 1940, over which I had the honour to preside, the Society passed a unanimous resolution stating that in its opinion

at least half the injuries to the eyes of our fighting men would be prevented were they wearing the vizor invented by Richard Cruise.

Here we have two conflicting opinions. The Medical Research Council decide that a sheet of cellophane is sufficient to avert injuries to the eye by flying fragments of steel; the Ophthalmological Society think that a plate of duralumin is necessary. I leave it to the common sense of the readers of this *Journal* to decide between these two opinions. The Cruise vizor was invented during the last war, but the War Office did not adopt it. Every ophthalmic surgeon who treated wounded eyes during the war knows what the result was: hundreds of men were blinded and many more received serious injury. Some at least of the might have been saved by the vizor. Since that time Sir Richard has greatly improved the vizor, and in its present form it affords a very high degree of protection. It consists of a plate of duralumin perforated by small holes. It is fitted to the steel helmet between the steel shell and the interior bandeau. With a tweak of the fingers it springs down, covering the top of the nose and the eyes. My own tests have shown me that when I wear it I can read the last row of the test types, 6/3, with ease, and that a myope can see better through the holes than with a naked eye. Tests with a choke-bore shotgun show that duralumin is hardly dented at twenty yards. Would the cellophane anti-gas eye-shield keep these shot from perforating the eye? The question is ridiculous. However, the War Office has decided that our soldiers are to have no protection for their eyes under conditions when they might use the vizor, so must leave it at that.

Let us turn to the civil population—the police forces, the fire-fighters, A.R.P. men, and the general public who act as fire-watchers. These are expected to approach incendiary bombs many of them explosive, and extinguish them. They are recommended when approaching a fire-bomb to hold a sandbag before their eyes, or to use the lid of a dustbin. Now, to begin with they do not carry dustbin lids about with them, nor sandbags, but they do wear steel helmets. If these were provided with a Cruise vizor they could snap it down and approach the bomb knowing that their eyes were reasonably safe. The dustbin lid would be perforated by the fragments of the bomb propelled by high explosive, and the sandbag is a heavy semi-solid mass needing two hands to lift it and hold it up. How could one do anything to a bomb when holding up a sandbag with two hands or when holding a dustbin lid unless it were perforated with sight-holes?

Perhaps it may be argued that eye injuries are not common in air raids. I would refer you to the paper published in the *Journal* of June 28 (p. 966) by my colleague at Coventry, Mr. Dorothy R. Campbell, in which she describes her experience after the raids on Coventry. During the past two months I have been acting as Regional Ophthalmic Adviser to the Ministry of Health, and it has been my duty to visit Emergency Hospitals in the Midlands and examine eyes injured during the blitzes. I have also seen cases at the Birmingham Eye Hospital and elsewhere. The facts are that after every raid a large number of eyes are injured: some slightly, some seriously; a some are blinded. A considerable number of these injuries have been sustained by attacking fire-bombs which have exploded. Two of my patients were blinded in both eyes from this cause, and both would have been saved by the Cruise vizor.

A well-known chain-store has recognized the necessity for some protection, for they had on sale, and may now have, an eye-shield of steel with a central adjustable crucial peep-hole. This is good, but the opening is too large and the shield cannot be attached to the helmet. In my own village I have a fire-watching corps, and the members ask for a vizor but cannot obtain it. I have heard that certain fire-constables have tried to get the Cruise vizor for their men but have not succeeded. What is the objection to this excellent protective device? It cost 3s. 6d., it weighs about two ounces and is quite perfect for its job. Is there no possibility that the Government, or the public services who want it, can be allowed to buy it? Perhaps a chain-store would market it. The fact is there: the public want it, and cannot get it, but must run the risk of blindness. It is a Gilbertian situation. Men are being blinded by bombs; there is a certain protection, it cannot be obtained. Can anything be done? Must this risk of blindness go on being

an expert committee consider that a bit of cellophane will keep out fragments that will perforate a bit of three-ply at twenty yards?—I am, etc.,

Birmingham, July 8.

T. HARRISON BUTLER, F.R.C.S.

* * We published an article by Sir Richard Cruise on his vizor in the *Journal* of May 18, 1940 (p. 825). In an annotation in our issue of June 1, 1940, we stated: "Protective vizors are indeed a greater need now than in the last war. . . . There are thus vital reasons for effective vizors as part of the civil defence outfit no less than that of the combatant."—ED., *B.M.J.*

Staphylococcus aureus in Nasopharyngeal Infections

SIR.—I am gratified at being quoted in your excellent leading article on acute otitis media (July 5, p. 20). With regard to the question "whether *Staphylococcus aureus* attacks the middle ear as a primary nasopharyngeal infection," I believe never. My opinion is based upon making cultures at operation over a period of twelve years by the method mentioned by you. I have not found *Staphylococcus aureus* before the eighth week, except where the technique was faulty, and it might have been picked up from the skin. I believe, therefore, that it must be added to the organisms causing cutaneous infection, which are always secondary to the nasopharyngeal ones after perforation of the drumhead.

If, therefore, all nasopharyngeal infections were got well by the end of eight weeks of the date of perforation, cutaneous (chronic) otitis media would die out in the course of a generation. Chemotherapy will, I believe, help us to approach this ideal. Once chronic disease has resulted it is, in my opinion, an incurable disease except as the result of the processes of Nature at some time in the life of the human being, which, I believe, is between 14 and 18.—I am, etc.,

Guy's Hospital, S.E. 1, July 9.

T. B. LAYTON.

Dangers of Posterior Pituitary Extract in Labour

SIR.—Your annotation on the dangers of posterior pituitary extract in labour (May 3, p. 675) states: "It is to be noted that in the discussion following the papers no speaker rose to defend it." May I call your attention to the remarks made by Dr. D. P. Murphy of Philadelphia (*J. Amer. med. Ass.*, 1940, p. 1325) on this subject: "The danger which results from the improper use of solution of posterior pituitary is more a problem of dosage than a question of which patient should receive it, and for that reason I think that those who oppose its use have missed the point entirely. Solution of posterior pituitary has a place in the treatment of certain patients in labour, but only when a non-tetantizing dose is employed, and that dose is in the neighborhood of 1-2 minims." Following Dr. Murphy's discussion I remarked: "The introduction of solution of posterior pituitary more than twenty-five years ago as a means of initiating and reinforcing labour pains constitutes a landmark in the development of the science and art of obstetrics."

May I also refer in this respect to the opinion of Dr. Fr. Irving, professor of obstetrics at Harvard, as expressed in his article in the *Amer. J. Obstet. Gynec.* for November, 1940: "We have used solution of posterior pituitary in the first and second stage of labor in about 20,000 cases and have seen no harmful effect, neither in the mother nor in the baby." The magnitude of the subject requires stress on such authoritative statements.—I am, etc.,

Cincinnati, June 15

J. HOFBAUER.

Is the Safe Period Safe?

SIR.—The safety of the safe period is again being questioned (July 5, p. 23). Much wider agreement on its usefulness would result from a knowledge of its limitations. It is applicable to women with regularly recurring menstrual cycles who lead regular or rather uneventful lives, but no reliance can be placed in it: (1) for up to six months after a miscarriage or confinement; (2) immediately after febrile diseases or an accident; (3) after drastic alteration in ordinary routine, such as change of climate or severe exertion; (4) after emotional upsets or long partings.

The even tenor of university life has provided numerous and unchallengeable records of the success of the method under ideal conditions.—I am, etc.,

London, W.1, July 7.

REYNOLD H. BOYD.

Silicosis without the Crystal Unit of Quartz

SIR.—In a recent paper entitled "Fibrotic Nodules in the Tracheobronchial Lymph Glands of the Mouse Produced by Breathing Precipitated Silica" (*Brit. J. exp. Path.*, 1941, 22, 76) it was demonstrated that silicotic nodules can be produced by silica precipitated from sodium silicate by nitric acid. Since there was some doubt as to whether or not this precipitated silica was amorphous, a sample of it was sent recently for analysis to the Physics Department of the National Physical Laboratory. I am indebted to the acting superintendent for the following report: "We find that the sample of silica supplied for test with your letter of June 30 does not give an x-ray spectrum. The material is, therefore, amorphous and does not possess any characteristic crystalline unit of appreciable definition or size. We regret that the x-ray test for quartz in this case is not applicable."

The conclusion from this is that natural crystalline quartz is not essential for the production of the silicotic nodule, since it has been produced also by an amorphous precipitated silica. Previously Drs. Gye and Purdy (*ibid.*, 1922, 3, 75) found that colloidal silica produces some degree of fibrosis, but so far as I know it did not produce the nodule. It is probable that, when administered appropriately in the correct dose and for a sufficiently prolonged period, colloidal silica would also produce the nodule.—I am, etc.,

London, N.W.3, July 5.

J. ARGYLL CAMPBELL.

The National Loaf

SIR.—The Medical Research Council has issued two documents recently in connexion with the above. In the first it was stated that the addition of calcium was necessary because of the unsatisfactory condition of the bones of part of the population. If this disease does not merely exist in imagination, let the authorities produce and exhibit, say, a dozen adults suffering from it at the Royal Society of Medicine. In the second document the addition of calcium is advocated because of war conditions—inadequate milk, etc. Now there is no evidence whatsoever that the population is suffering from calcium deficiency: it can be said definitely that there is no calcium deficiency. Under present conditions we are short of many substances. Why then is the loaf to be "fortified" with this substance only? It will be remembered that originally the scheme was meant as a permanent "reform," based on pre-war conditions. Now it is advocated merely as a war measure, for which not a scintilla of evidence exists that it is necessary. If I can trust my memory, according to a statement of Lord Woolton the milk consumption at present still does not fall below the pre-war level. In any case milk contains as many items of food as vital as calcium. As in any case an adequate supply of this article of diet is necessary for the sake of the many vital items it contains, the requisite calcium will be forthcoming. Moreover, all available evidence points to the fact that calcium is ineffective without vitamin D. Those of us who have experimented with substances such as calcium have become convinced that its action depends to a vital extent on a number of other items contained in the diet. To concentrate on one item and neglect others as vital as this is scientifically unsound—indeed, the whole scheme has all the characteristics of a nostrum. It would be better if the Government were to make it compulsory to swallow calcium in pill form—in this way at least it would be ensured that each individual got the same dose. But under the proposal, since some people eat twenty times more bread than others they would get twenty times more calcium.

It is a sound physiological principle that the consumption of substances in quantities greater than required is not conducive to good health. According to the Medical Research Council there is no evidence that the added calcium can do harm in any type of disease. But surely this is not enough. The authorities must make sure that chalk can effect no injury in any circumstances. They must prove this, for forty million people cannot be used as experimental rabbits. I know the assertion that

added calcium can do no harm in any type of disease is contrary to actual facts. A large amount of work—some of it dating a generation back—has proved conclusively that under certain conditions calcium is injurious to health. Public interest demands that an exhaustive inquiry into the matter should be instituted by a board comprising men familiar with different aspects of the problem—physiologists, physicians, pathologists, biochemists, food experts, pharmacologists. Members of this body ought to have no connexion with the Medical Research Council or the Food Ministry. The inquiry should be open and detailed evidence published. I trust that the Government proposals will not become effective until the pronouncement of such a body becomes available. The British Medical Association would render a public service by instituting such an inquiry under its aegis.—I am, etc.,

Liverpool, July 9.

I. HARRIS.

Differential Diagnosis of Contusion of the Brain and Psychoneurosis

SIR,—My excuse for this note is that I had the good fortune to call in the late Wilfred Trotter to see a head injury case. He gave me a private lesson. On my asking him how he diagnosed contusion of the brain, he answered, "Headaches, brought on especially by changes of posture—for example, stooping, sneezing, coughing, etc.—giddiness, mental apathy, mental degeneration, and congestion of the retinal veins." Whereupon I asked him how he came to a decision about congestion of the veins. With a twinkle in his eye he replied, "That comes with experience, and after that you fix your own index."

I regret that, despite this lesson, the mysterious secrets of the retinal veins have not yet been successfully fathomed by me. Finally, I have also had the advantage of seeing a number of head injuries with Dr. W. A. Brend in the last fifteen years.—I am, etc.,

Solva, Pembrokeshire, July 8.

J. STEPHEN LEWIS.

Ether Convulsions

SIR,—I have been very much interested in the correspondence on this subject, as I have seen a few cases since the war when I have had to operate in overheated, sandbagged, and steaming theatres, and when the anaesthetic administered has been ether. Three cases were serious and one ended fatally. I agree with Mr. Charles Wells's description (June 21, p. 945) of ether convulsions as being typically expiratory, and I would like to add that, in my experience, the correct procedure is the immediate administration of chloroform. I have always found the convulsions cease almost at once, and the fatal case I mentioned happened when there was no chloroform available. I have had no experience of the use of evipan for this purpose.—I am, etc.,

Newport, Mon., July 7.

J. T. RICE EDWARDS,
Surgeon, E.M.S.

Trichlorethylene as Anaesthetic

SIR,—In view of the large number of anaesthetists who have written to the makers for supplies of trichlorethylene following the publication of our paper in the *Journal* of June 21 (p. 924), we feel that a note of warning might not be amiss.

While we are only too glad for as many workers as possible to try out this drug, we must make it quite clear that we cannot accept responsibility for any untoward effects that may occur. As mentioned in the paper, the total number of administrations made so far is much too small for any definite conclusions as to safety, etc., and the individual anaesthetist must accept the responsibility himself.—We are, etc.,

C. F. HADFIELD,
C. LANGTON HEWER.

St. Albans, July 10.

The Middlesex Hospital has received, as a gift from the Scarsdale (New York) Branch of "Bundles for Britain," a mobile x-ray set and four portable theatre lights. This new equipment, of the latest design, enables work to be transferred quickly to a basement or sub-basement in the event of an upper theatre being wrecked.

Obituary

SIR WILLIAM H. WILLCOX, K.C.I.E., C.B., C.M.G.,
M.D., F.R.C.P.

Consulting Physician, St. Mary's Hospital

The death of Sir William Willcox, which took place suddenly and peacefully on July 8 at his home in Welbeck Street, W., where he had carried on a consulting practice for many years, removes from the foremost rank of his profession a highly individual figure. To the man in the street, or in the public galleries of courts, the name of Willcox stood out from the general anonymity of the medical profession owing to his appearance over many years in famous criminal cases. But the same exceptional industry and knowledge which he brought to toxicology in particular and forensic medicine in general he devoted also to the clinical study of disease, and he once declared that to him rheumatic fever or acute rheumatism was the most fascinating subject in the whole of medicine.

William Henry Willcox was a native of Melton Mowbray. Brought up in the heart of a famous hunting country, he never lost his love for the horse and the open—indeed, in late life his horseback exercise cost him a severe accident—and his build and countenance always suggested the robust country squire. He was educated at the Wymondham Grammar School, Oakham, and then at the Wyggeston School, Leicester, and from there he went to University College, London, and to St. Mary's Hospital Medical School. His college career was brilliant. He was gold medallist in anatomy, organic chemistry, materia medica and therapeutics, and forensic medicine, and at St. Mary's he gained the Cheadle gold medal for clinical research. He took his M.B.Lond. in 1900, and proceeded M.D. in the following year, taking also the diploma in public health. From 1904 to 1906 he was medical registrar at St. Mary's, and a year later was elected to the visiting staff of that hospital, so remaining until 1935, when he was made consulting physician. In the war of 1914-18 he served as consultant to the armies in Mesopotamia, and was four times mentioned in dispatches and received the C.B. and C.M.G. There he accumulated fresh clinical experience, especially with regard to malaria, on which he continued to draw for the rest of his life.

His appointment as medical adviser to the Home Office dated from 1919, though he had been associated with the late Prof. Pepper in many criminal cases before then. This brought him into prominence in Crown prosecutions. He was the most deliberate and painstaking expert witness who ever stepped into the box. His hesitating manner at first produced an unfortunate impression, and occasionally even aroused irascibility in a judge who did not know him well. But it soon came to be taken for granted in the legal profession that this slowness of speech was due to conscientiousness and sense of responsibility. The present writer recalls his appearance at the famous Hadwen trial at Gloucester in 1924. When he began his halting testimony one wondered whether at the end of the evidence for the

prosecution the jury might not stop the case, but it gradually dawned on the court that, few as were his words, they each of them, as Morley said of Gladstone's, weighed a pound, and the tilts of Sir Edward Marshall-Hall for the defence made no dent at all in that heavy armour. At about that same time, at a meeting of the Hunterian Society, Willcox gave a description of the duties of a medical witness; it is too long to quote here, but it could not be bettered.

It was the same in his public utterances: he would make a hesitating beginning, and one was inclined to think that he was talking complimentary nothings when there would come a shrewd clinical observation, a description of an unusual case, an exposition of some aspect of pathology, or a warning against a drug fashion of the moment. At the time when the barbiturates came into common use Willcox made up his mind once for all, and never lost an opportunity to warn the profession against their indiscriminate employment. In recommending vaccines, too, he never tired of urging the greatest care lest some condition such as exophthalmic goitre had sensitized the body. Again with anaesthetics, he held that avertin should only be used by the most experienced, and by them with the greatest caution, owing to its liability to cause liver damage. No one was more cautious, painstaking, and exhaustive in what he undertook. His writings are spread over medical journals and the transactions of societies, but even casual communications are marked by thoroughness, and in such a contribution as the Lumleian Lectures to the Royal College of Physicians in 1931 the subject—toxic jaundice—was so fully explored that there seemed to be nothing left to be said. The lecture table was his chosen medium for imparting knowledge. At St. Mary's for thirty years he was lecturer on chemical pathology, and for almost the same period on forensic medicine.

He was a member of the British Medical Association for thirty-five years. In 1932, the year of the Association's Centenary, he was president of the Section of Forensic Medicine, and made a plea for more public recognition of that subject, particularly urging his old University of London to establish a professorial chair. When the Annual Meeting was held at Melbourne in 1935 he was president of the Section of Pharmacology, Therapeutics, and Anaesthetics. On that occasion Melbourne University conferred on him its M.D. *honoris causa*. Ten years ago he was chairman of the Marylebone Division, and he served on a number of special committees at headquarters, notably one on causes and treatment of arthritis, and another on tests for drunkenness. There were few medical societies in London whose chair he had not filled. He was president of the Harveian Society in 1922, of the West London Medico-Chirurgical Society in 1923, of the Medico-Legal Society in 1928, and of the Medical Society of London in 1936, when he delivered a noteworthy presidential address on clinical immunity. During the last two years he had been president of the Section of Therapeutics and Pharmacology of the Royal Society of Medicine. In 1935 he was Master of the Society of Apothecaries, of which he had become a licentiate thirty-six years before. He was elected F.R.C.P. in 1910, and served on the Council of the College in 1931-3. Other offices which he held were those of examiner in pharmacology and therapeutics to the University of Cambridge and visitor for the Privy Council to the examinations of the Pharmaceutical Society. He was senior physician to the London Fever Hospital and to St. Luke's Hostel for the Clergy. The latter benevolent enterprise was very near his heart. He was a man of great kindness and of unlimited private generosity.

The honour of knighthood in the Order of the Indian Empire was bestowed upon him in 1921. He married a Northamptonshire lady, who survives him with three sons and a daughter.

F. G. LAYTON, M.R.C.S.

The sudden death of F. G. Layton on July 3 removes one of the best-known figures in the medical profession of the Midlands. Born in 1872, he was the son of the vicar of a South London parish; he was educated at King's College School, London, and at St. Thomas's Hospital; took the M.R.C.S., L.R.C.P. in 1894; and filled resident appointments at his own hospital, Brompton, and Great Ormond Street. Settling at Walsall, he identified himself with the Walsall General Hospital, to which, at the time of his death, he was consulting physician. He took a prominent part in local public life and was a Justice of the Peace, an office in which he took a special interest, as is shown by his book *Psychology in Court*. He had a very prolific pen, and wrote several books dealing in a light but sympathetic vein with the life of a general practitioner among poor folk. These included *The Little Doctor* and *Behind the Night Bell*. He also for many years edited the *Midland Medical Journal*. He joined the British Medical Association in 1895, and took an active part in its local work. From 1913 to 1922 he was honorary secretary of the Walsall and Lichfield Division. In 1935-6 he was chairman of the Division, and at the time of his death was president of the Staffordshire Branch.

DR. ALFRED COX writes:

The death of Layton brings back many recollections of happier times when he was not only the life and soul of B.M.A. activities in his Division but a most watchful and constant critic of our activities at headquarters. He was essentially an individualist, but combined with his individualism a strong sense of his duty to the community and a real love and understanding of the "under-dog." This he showed both in his life and in his books, which could only have been written by a real "family doctor" whose sense of his responsibilities to his patients was equalled by his sense of humour. With Layton the style was essentially the man both in writing and conversation.

In the early days of the new constitution Walsall was not an easy district from the B.M.A. point of view, and had it not been for Layton its record would have been much less honourable than it is. He used his pen and his tongue on his colleagues just as he did on us at the office; but all of us took his jibes and criticisms more or less meekly just because they came from Layton and because we knew his bark was worse than his bite. He had a horror of "bureaucracy," and used to chaff me unmercifully (in letters which were always a joy to receive and to answer) about the style of our official communications. More than once he sent me a free translation of such documents as they should have been written (in Laytonese) and as a model to which we ought to aspire.

His long B.M.A. record deserves handsome recognition, for the labours of such men as he have made the path of their successors so much easier. But those of us who knew him well and loved him will always think of Layton the man—honest, direct, and always arriving like a breeze of fresh air whenever he appeared on the scene either personally or in writing.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The following candidates have been approved at the examination indicated:

FINAL M.B.—Part I (Surgery, Midwifery, and Gynaecology): R. M. Archer, J. D. Attwell, R. C. Barclay, D. V. Bateman, K. F. C. Brown, L. J. H. Burton, H. Butler, W. H. Chase, R. E. W. B. Comerford, E. D. Cullen, P. M. Daniel, B. Dansie, F. M. P. Eckstein, E. J. S. Evans, C. L. Grandage, R. E. A. S. Hansen, D. V. Harris, A. Holmes-Smith, E. B. Jarrett, R. Jenkins, J. S. Johnstone, K. H. Lim, L. R. McLaren, H. L. McMullen, J. M. Mungavin, P. H. Nash, T. P. Pattinson, A. G. E. Pearce, G. E. Pinkerton, G. K. Riddoch, P. Sainsbury, J. L. S. Smith, A. G. Stansfeld, J. H. Tasker, H. D. Teare, D. E. Thompson, D. G. Vulliamy, A. Waymouth, H. G. Wolskel. **Women:** H. M. Comely, A. Davies, D. H. King, M. Redfern Davies.

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.—Part II: M. Altmann, R. D. Caion, A. Elkeles, J. E. Glasgow, Mrs. Grace M. Griffith, M. Halberstaedter, P. C. Phelps.

UNIVERSITY OF ABERDEEN

At a graduation ceremony on July 10 the honorary degree of LL.D. was conferred on Dr. Arthur Wellesley Falconer, C.B.E., D.S.O., M.D., F.R.C.P., Principal and Vice-Chancellor of the University of Capetown (*in absentia*).

The following medical degrees and diplomas were also conferred:

M.B., Ch.B.—*G. E. Swinney, *A. R. Taylor, T. M. Allan, A. L. S. Anderson, Marie L. Anderson, J. B. Barnett, W. H. F. Boyd, A. A. Brockie, B. E. Brocks, J. L. D. Brown, J. Bruce, N. B. Carmichael, Alison Clarke, A. M. W. Coburn, H. D. Collins, J. Cramond, J. Cran, Eunice M. Duncan-Brown (*née* Auty), A. H. Dunnett, Marguerite N. L. Erskine, J. W. Gammie, A. G. Gibb, R. A. S. Gibb, Vera W. D. Hall, Helen D. Harkins, J. A. Harrow, G. A. M. Hendry, M. I. Hepburn, T. Hunter, F. L. F. Innes, J. M. E. Jewers, P. O. Leggat, J. J. McNair, J. G. Matheson, R. F. Menzies, P. Milne, W. H. P. Minto, R. G. Murray, K. O'Brien, J. Slater, A. Stephen, Florence Stewart, W. D. Swinney, P. Theron, E. J. Valentine, S. W. Watson, R. A. S. Watt, Lily White, Margaret O. Will, D. MacG. Williamson, L. A. Wilson, A. J. Witt, J. F. Woolcott.

DIPLOMA IN PUBLIC HEALTH.—W. Lamb, J. A. F. McLean.

* Second-class honours.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Message from the King

The following letter from the King's Private Secretary has been received by the Royal College of Surgeons of England and was read to the Council at a meeting held on July 10:

Dear Sir Hugh Lett,

I write to thank you for your letter of yesterday, which I have laid before the King as Visitor to the Royal College of Surgeons of England. I am to assure you that it is a source of deep regret to His Majesty to learn of the damage to the Museum buildings and the loss of valuable specimens resulting from enemy action. The King is, however, much gratified to hear of the further generous gift made by the Bernhard Baron Trustees towards the endowment of the professorship of research which will go far to prevent any of the regrettable interruption which might otherwise have occurred in the scientific work and development of the College.

Yours very truly,
(Signed) A. H. L. HARDINGE.

Election of President

At a meeting of the Council of the Royal College of Surgeons of England, held on July 10, with Sir Hugh Lett, President, in the chair, Sir Alfred Webb-Johnson was elected President for the ensuing year, and Surgeon Rear-Admiral G. Gordon-Taylor and Mr. L. R. Braithwaite were elected Vice-Presidents. Prof. A. H. Burgess, Mr. H. S. Souttar, and Mr. V. Zachary Cope were readmitted, and Mr. E. Finch was admitted to the Council.

Lecturers

The following professors, lecturers, and demonstrators were elected for the ensuing year:

Hunterian Professors.—Surgeon Rear-Admiral G. Gordon-Taylor, one lecture on the Surgical Anatomy of the Lower End of the Common Bile Duct and the Adjacent Head of the Pancreas; Surgeon Rear-Admiral C. P. G. Wakeley, one lecture on War Burns; Lieutenant-Colonel A. E. Hamerton, one lecture on Primary Degeneration of the Spinal Cord in Monkeys; Mr. W. T. Warwick, two lectures on Observations on the Growth of Long Bones; Prof. F. Davies, one lecture on the Conducting System of the Vertebrate Heart; Mr. N. Asherson, one lecture on the Orogenic Cerebellar Abscess, with Special Reference to its Operative Treatment and the Posterior Fossa Cerebrospinal Fluid Syndrome; Surgeon Commander E. R. P. Williams, one lecture on Blast Injuries in Warfare; Mr. A. Sorsby, one lecture on Aetiology of Pteryctenular Ophthalmia; Mr. J. T.

Chesterman, one lecture on Evaluation and Treatment of Factors involved in Post-lobectomy Collapse of the Lung; Mr. F. W. Willway, one lecture on the Role of Surgery in Mental Disease; Mr. D. N. Matthews, one lecture to Investigate the Value of Sulphanilamide and Sulphathiazole applied locally to Infected Wounds and Burns.

Ariss and Gale Lectures.—Prof. J. Beattie, two lectures on Physical and Chemical Changes in the Blood associated with Shock and Haemorrhage; Dr. D. P. Cuthbertson, one lecture on Certain Aspects of the Physiological Reaction to Injury—the Post-shock Metabolic Response.

Erasmus Wilson Demonstrators.—Mr. L. E. C. Norbury, two demonstrations on the pathological contents of the Museum; Mr. R. Davies-Colley, two demonstrations; Mr. C. E. Shattock, two demonstrations.

Arnott Demonstrator.—Mr. A. J. E. Cave, six demonstrations on the contents of the Museum.

Appointments

Sir Frank Colyer, Honorary Curator of the Odontological Collection, and Mr. C. J. S. Thompson, Honorary Curator of the Historical Collection, were reappointed for the ensuing year.

The Hallett Prize, granted on the result of the Primary Examination for the Fellowship, was awarded to S. Oleesky of the University of Manchester; the twelfth Macloghlin Scholarship was awarded to D. L. Kerr of Whitgift School, Croydon; and a Leverhulme Scholarship was granted to Miss H. B. Collard for a year beginning August 1, 1941. Subject of research: Study of the change in blood volume following haemorrhage.

Diplomas

Diplomas were granted, jointly with the Royal College of Physicians of London, as follows:

DIPLOMA IN PUBLIC HEALTH.—C. A. Boucher, M. Coke, Nancie I. Faux, H. J. Griffiths, W. E. MacDougall, H. C. Price.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—R. A. Blair, Edith M. Booth, E. W. Dunkley, A. M. Edwards, S. T. Hayward, J. J. H. Lowe, J. S. McGregory, Sigrid M. Pribram, W. A. M. Robinson, J. S. F. Sutton, Mary E. E. Ward.

DIPLOMA IN LARYNGOLOGY AND OTOTOLOGY.—D. A. Barley, N. L. Crabtree, O. C. Lord, J. E. Rees.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At a meeting of the Royal Faculty of Physicians and Surgeons of Glasgow, held on July 7, with Mr. Roy F. Young, President, in the chair, A. McPhater, M.B., Ch.B., and H. H. Pinkerton, M.B., Ch.B., D.A., were admitted Fellows of Faculty.

The Services

ARMY AWARDS

The following honours have been conferred in recognition of distinguished services in the Middle East during the period December, 1940, to February, 1941:

C.B. (Military Division): Colonel (Temporary Major-General) P. S. Tomlinson, D.S.O., late R.A.M.C.

C.B.E. (Military Division): Lieutenant-Colonel (Temporary Colonel) F. G. A. Smyth, O.B.E., R.A.M.C.

O.B.E. (Military Division): Major (Temporary Lieutenant-Colonel) B. J. Daunt, R.A.M.C.

M.B.E. (Military Division): Captain (Temporary Major) P. L. E. Wood, R.A.M.C.

MENTIONS IN DISPATCHES

The following have been mentioned in dispatches for distinguished services in the Middle East during the period December, 1940, to February, 1941.

Army Medical Corps: Lieut.-Colonels A. J. Cunningham (since deceased), H. G. Furnell, D.S.O., and L. E. Le Souef; Majors E. Bailhache (since deceased) and J. O. Smith; and Captains L. V. Armatti, K. J. J. Dorrey, N. R. Godby, and R. H. MacDonald.

Royal Army Medical Corps: Major (Temporary Lieutenant-Colonel) D. Bluet; Captains (Temporary Majors) D. R. Hood, R. B. Robertson, and R. A. Stephen; and Captains W. J. A. Craig, T. G. S. James, J. J. Justice, R. H. Spurrier, and M. H. Webster.

Indian Medical Service: Lieut.-Colonel A. N. Sharma; Captain (Temporary Major) J. Revans; and Captains D. R. Cattanach, R. Y. Taylor, and D. D. Verma.

New Zealand Army Medical Corps: Captain A. L. Lomas, M.C.

Temporary Surgeon Lieut. John Fawcett Hughes, R.N.V.R., has been mentioned in dispatches for good services when H.M.S. *Exmoor* was sunk.

CASUALTIES IN THE MEDICAL SERVICES

ROYAL NAVY

The name of Surgeon Lieut. DUNCAN LORIMER, R.N.V.R., is included in an Admiralty casualty list published on July 9 as "Missing, Presumed Killed" in H.M.S. *Jersey*. After graduating B.A. at the University of Cambridge in 1935 he studied medicine at the University of Edinburgh, where he took the degrees of M.B., Ch.B. in 1938. He was a member of the British Medical Association and of the Royal Medical Society of Edinburgh.

Surgeon Commander ARCHIBALD ROBERT EWART, R.N., lost his life by enemy action at sea in June. He was the eldest son of the late Mr. Thomas Ewart and Mrs. Ewart of Limerick, and was educated at the University of Dublin, where he graduated M.B., B.Ch., B.A.O. in 1928. Soon afterwards he entered the Royal Navy as surgeon lieutenant, was promoted to surgeon lieutenant-commander in 1934, and to surgeon commander last year. He had been a member of the British Medical Association since 1929.

Surgeon Lieutenant ARCHIBALD THOMAS LEGGATE has been killed by enemy action while on active service. He was last seen attending the wounded on the deck of his vessel and went down with the ship. Dr. Leggate, who was 30 years of age, was the third son of Dr. and Mrs. Leggate of Liverpool, and his wife, whom he married recently, was formerly Dr. Joan Thomson. He had a distinguished scholastic career. At Liverpool College, where he was a member of the First rugby and cricket teams, he was awarded many prizes and won a scholarship to Emmanuel College, Cambridge. At that stage his main interests were philosophy and history, and he seemed destined for the Church. The family tradition of medicine, however, proved too strong, and after graduating at Cambridge he entered Liverpool University and qualified M.B., Ch.B. (with distinction in surgery) in 1937. Following a period as house-physician at Liverpool Royal Infirmary, he helped in his father's practice, and rapidly became a most conscientious and resourceful practitioner, combining dignity and knowledge with good humour and understanding. It was doubtful whether he intended to stay in general practice, and specialization in psychiatry greatly attracted him. Archie Leggate (writes a colleague) had an exceptionally wide range of interests—music, history, and literature—and amongst his major delights he always counted the wild grandeur of the North-West Highlands. Transcending all was his love of humanity; he had tremendous faith in man and in the ultimate triumph of truth and goodness. Essentially a man of peace, he became imbued with the courageous spirit of a Crusader, and with conviction based on the highest Christian ideals he joined the R.N.V.R. at the outset of the war.

In an Admiralty casualty list published on July 9 Probationary Temporary Surgeon Lieut. ALAN KENNETH BEARDSHAW, R.N.V.R., is posted as "Missing, Presumed Killed" in H.M. Yacht *Fiona*. He was educated at the University of Sheffield, where he graduated M.B., Ch.B. in 1938. He was a member of the British Medical Association.

ROYAL AIR FORCE

Acting Squadron Leader DAVID ALAN HOPE ROBSON was killed in June. He was born on July 11, 1908, and received his medical education at the University of Edinburgh, graduating M.B., Ch.B. in 1933. After holding house appointments at the Children's Hospital and City General Hospital, Sheffield, he spent four years in general practice at Beddington, Surrey, and became honorary medical officer to the Carshalton and Beddington War Memorial Hospital. He entered the Medical Branch of the Royal Air Force on a short service commission, and served in France from September, 1939, until April, 1940, when he was posted to an operational unit. Acting Squadron Leader Robson was keenly interested in flying, and qualified as a pilot in February, 1941.

Flight Lieut. DENIS WILLIAM MAHON was seriously injured in June, and died shortly afterwards. He was born on February 19, 1915, and received his medical education at the London Hospital, qualifying M.R.C.S., L.R.C.P. in 1938. He was a member of the O.T.C. After holding the post of demonstrator in applied physiology, histology, and applied pharmacology at the London Hospital Medical College and house appointments at Poplar Hospital, and the Royal Berkshire Hospital, Reading, he was commissioned in the R.A.F.V.R. on November 28, 1939. From February till June, 1940, he served in France, and since then had been medical officer to a bomber squadron.

Medical Notes in Parliament

The National Health Insurance, Contributory Pensions, and Workmen's Compensation Bill was introduced by Mr. ERNEST BROWN on July 1 and was read a first time. Its purposes are "to increase the rates of sickness and disablement benefit and the rates of contribution payable under the Acts relating to National Health Insurance, to extend the said Acts to persons employed otherwise than by way of manual labour at a rate of remuneration exceeding £250 a year," and also to make changes in the Acts relating to Pensions and Workmen's Compensation. The text of the Bill is published.

Speaking in a debate on production on July 9, Mr. HAROLD MACMILLAN said the Ministry of Supply was buying medical and surgical supplies for the Air Force.

Research into Gas Decontamination of the Eyes

Mr. HAROLD MACMILLAN, replying on July 8 to Mr. Groves, said research on the medical treatment of gas casualties had been carried out in the Chemical Defence Research Department and elsewhere by teams of fully qualified men, with the personal assistance and supervision of well-known research workers in the physiological and pharmacological fields. The findings of these workers had been scrutinized by a medical committee consisting of distinguished civilian specialists and Service medical men, to which additional specialists had been co-opted. Increasing pressure of work on eye treatment was found in the summer of 1940 to necessitate the whole-time employment of an ophthalmological specialist, but owing to the difficulty of obtaining a suitably qualified man this appointment was not made till August, 1940. It was then also found possible to engage the assistance in addition of leading ophthalmologists, working in independent laboratories. The intensive research which thereby became possible included re-examination of all methods tried previously.

Fracture and Orthopaedic Treatment in Scotland

On July 8 Mr. JOHNSTON, replying to Dr. Morgan, said that while he was aware that facilities for fracture treatment in Edinburgh and Glasgow were not generally in full accordance with the recommendations of the Delevingne Committee, some progress had been made since the publication of the report. Moreover, in developing the Emergency Hospital Services special attention had been given to arrangements for the treatment of fractures, including the provision in Scotland of six entirely new orthopaedic units (with associated provision for occupational therapy providing 2,000 beds). As announced by the Minister of Health on April 3, these facilities were available not only for the treatment of civilian war casualties but for certain manual workers whose early return to work was of special importance. As regards conditions which occasioned crippling other than fractures, he had encouraged schemes initiated by voluntary bodies for the improvement and extension of facilities for their treatment. He was not aware of any official report on this subject other than that of the Delevingne Committee.

Care of Wounded in Invasion

On July 8 Mr. GROVES asked the Minister of Health if he would state the arrangements made by the A.R.P. for the care of wounded civilians in the event of invasion making road or telephone communication impossible over large areas, particularly in those coastal regions upon which the brunt of invasion might be expected to fall. Mr. BROWN said that the arrangements made to meet the contingency described could not in the national interest be set out in detail, but his Regional Officers and the scheme-making authorities had been fully alive to it when reviewing the first-aid posts, first-aid points, and ambulance services in their areas.

Children's Health in Camps.—Mr. JOHNSTON stated on June 25 that quarterly reports submitted by the camp medical officers showed residence at the camps provided in Scotland under the Camps Act, 1939, had a markedly beneficial effect on the health and physical condition of the children. Most gained in height and weight and had shown an increased resistance to infection. When Belmont Camp was reopened those children who returned were found to have lost in weight during their absence of three months.

Wartime Nurseries: Medical Supervision.—Mr. GROVES, having regard to the additional duties imposed upon medical officers of health by reason of the war, asked whether arrangements had been made or recommended for the services of available local general practitioners to be utilized for the regular medical inspection and supervision of the children at wartime nurseries. Mr. BROWN told Mr. Groves on June 24 that detailed arrangements for the medical supervision of children in wartime nurseries were a matter for the medical officer of health of the welfare authority establishing the nursery. Such arrangements would usually take the form of an extension of the authority's existing scheme for the medical supervision of young children, whether by whole- or part-time medical officers.

Notes in Brief

Mr. E. Brown told Mr. Viant on June 17 that of the 15 cases of post-vaccinal encephalitis which came to the notice of his Department in 1940, 5 were fatal. Two of the fatal cases were in soldiers. The others had recovered.

EPIDEMIOLOGICAL NOTES

Infectious Diseases for the Week

In England and Wales the incidence of enteric fever and cerebrospinal fever has declined slightly, and both diseases are now less prevalent than at this period last year. Dysentery and whooping-cough are on the increase and are respectively over twice and six times more prevalent than last year. The incidence of diphtheria has also shown a tendency to rise in the last two weeks. The persistent high incidence in Birmingham, where the same number—31—was notified in each of the last three weeks, and the virulent type of the prevalent infection, have been causing concern to the public health authorities. In the first six months of this year there were in Birmingham 600 confirmed cases of diphtheria compared with 336 last year, and 56 deaths compared with 16. Although facilities for immunization are ample and much advertised, it appears that less than one-half of the child population have been inoculated. In Scotland notifications of cerebrospinal fever have risen from 42 to 50; the principal notifiable diseases are less prevalent than in 1940, with the exception of whooping-cough and enteric fever.

Enteric Fever and Dysentery

Enteric fever is present in twenty-seven areas in England and Wales, compared with twenty-six in the previous week, but only in three were more than 10 cases notified—namely, Lancaster 45 (Blackpool 1, Bootle 9, Liverpool 26, Bacup M.B. 1, Eccles M.B. 1, Kirkham U.D. 1, Litherland U.D. 1, Urmston U.D. 1, West Lancashire U.D. 1, Widnes M.B. 3); Warwick 13 (Birmingham 7, Nuneaton M.B. 3, Solihull U.D. 2, Sutton Coldfield M.B. 1); Chester 11 (Birkenhead 7, Wallasey 3, Bebington M.B. 1). Although only slightly less prevalent than enteric fever, dysentery appeared in no more than sixteen areas, and in two only were there more than 10 cases—namely, Brecknock 40 (all in Brecknock M.B.) and Lancaster 27 (Blackburn C.B. 4, R.D. 13, Liverpool 2, Preston R.D. 1, Warrington R.D. 4, Whiston R.D. 3). In Scotland there were 4 cases of typhoid fever (Greenock 2, Motherwell and Wishaw 2), and 15 of paratyphoid B fever (9 in Dundee, and 1 each in the counties of Angus, Ayr, and Roxburgh, and in the burghs of Kirkcaldy, Glasgow, and Edinburgh). Dysentery was more prevalent, affecting the counties of Argyll 1, Lanark 5, Renfrew 1, Stirling 1, and the burghs of Aberdeen 9, Dundee 1, Glasgow 6, and Edinburgh 3.

Whooping-cough

Whooping-cough is present in every administrative area in England, and in one (Rutland 7) was the only disease notified during the week. Only the three Welsh counties of Anglesey, Cardigan, and Montgomery were free. Areas chiefly involved were Lancaster 519, West Riding of Yorkshire 443, Middlesex 334, Durham 330, Surrey 301, Essex 222, Derby 164, London 160, Kent 143, Warwick 143, Stafford 135, Northumberland 102, Northampton 101. In Scotland notifications were received from the county of Lanark 13, and the burghs of Glasgow 174, Edinburgh 40, Paisley 8, Dundee 8, Greenock 7, Rutherglen 7, Kirkcaldy 4, Aberdeen and Dunfermline 1 each, but this disease is notifiable only in particular areas when it is prevalent or a method of "intimation" is employed.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended June 21.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Includes primary form in figures for England and Wales, London (administrative county), and Northern Ireland.

† Owing to recent movements of population, birth and death rates can no longer be given for Northern Ireland.

Medical News

Papers on "Some Soviet Contributions to War Surgery" will be read by Dr. Janet Vaughan and Mr. Ruscoe Clarke, F.R.C.S., on Friday, July 25, at 7.30 p.m., at the Medical Society of London, 11, Chandos Street, London, W.1. Invitation cards may be obtained from the Society for Cultural Relations with the U.S.S.R., 98, Gower Street, London, W.C.1 (Euston 2315).

Owing to the large numbers of wounded German officers and men arriving back from the Russian front, the German Government has ordered the mobilization of Jewish doctors and nurses in the Third Reich to assist in the care of the wounded. Similar mobilization orders have been issued in Hungary, Rumania, and Slovakia.

The Association of Special Libraries and Information Bureaux (ASLIB) is undertaking a national survey of the present position concerning enemy and enemy-controlled publications, especially the current issues of periodicals. Previous inquiries have confirmed the impression that since the early part of 1940 only very limited supplies have been arriving in this country; that they consist mainly of imperfect sets of a few periodicals restricted very largely to departmental libraries that are not accessible to the general public; and that only a detailed survey can reveal the inadequacy of the present supplies. Through the good offices of the Royal Society, the Rockefeller Foundation has now provided funds for such a survey, which will be completed by a committee of the association by the autumn. A memorandum is being circulated to some two thousand institutions and individuals to ascertain what publications they need and the extent to which they are locally available. Those who do not receive a copy of the memorandum and are interested to do so should communicate with the ASLIB Foreign Periodicals Committee, 31, Museum Street, London, W.1.

A Venezuela Society of Microbiology, Parasitology, and Tropical Medicine has recently been founded at Caracas.

In 1940, 5,715 taxi-drivers in Germany had their licences withdrawn, in 1,672 cases owing to being drunk while driving.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS of their articles must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be addressed to the Secretary.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES: EDITOR, *Aitiology Westcent, London*; SECRETARY, *Medisecra Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Urticaria

"B. M. E." (Middlesex) writes: In reply to "H. S." (June 28, p. 922), a case of severe urticaria some years ago in which drugs were of no avail cleared up after a few doses of an autogenous intestinal vaccine, the organisms found being of the Gaertner group. There has been no return—the case had lasted some months.

Dysmenorrhoea

Dr. A. C. F. HALFORD (Brisbane) writes: I was very interested to read Mr. A. J. Hobson's advice (February 1, p. 182) to use calcium lactate for the relief of dysmenorrhoea. His prescription is the formula of the late Dr. Blair-Bell, *mistura calci lactatis recentis*, under which name Mr. Hobson's prescription may be written. I have used this preparation for many years, and have always

regarded calcium as a very useful drug for many conditions described in its pharmacology, notably in that valuable publication the *Extra Pharmacopoeia*. It is very effective at all stages of pregnancy, especially during the latter months, to remove oedema, albuminuria, headache, and cramp—pre-eclamptic states, in fact. *Liquor calci lactatis* (Martindale) is claimed to be a more stable preparation and so should be remembered. Calcium, combined with *tinct. cannabis indica*, both in full doses; should be tried out in all cases of menorrhagia before any surgical procedures are undertaken. And so also for dysmenorrhoea hot baths and plenty of exercise should take first place in therapeutics. Proprietary preparations are in no way superior to *calci lactatis recentis*, which is much cheaper.

Exercises for Arteriosclerosis

"J. B." writes: I should be grateful for advice in the treatment of the following case. A man aged 77 suffers from arteriosclerosis, chiefly in the right foot and leg, accompanied by some coldness, slight redness, numbness, and loss of sense of light touch in the toes. The pulse in the arteries at the ankle is imperceptible. Other symptoms are: claudication, pain, cramp, weight, and tired feeling in the calf on walking 150 to 200 yards. The kidney and liver are in good condition; blood pressure is 142/90; slight angina pectoris on exertion for seven years. Two years ago I saw it stated that Buerger's exercises were of "definite value." I should be glad to know if these are really useful. They require forty-five minutes thrice daily, and include: (1) raising and blanching the foot; (2) hanging and reddening it; and then (3) placing the limb in a horizontal position for three minutes in each cycle.

LETTERS, NOTES, ETC.

Nurse Anaesthetists

Dr. J. R. J. BEDDARD writes: Having read with great interest the correspondence concerning nurse anaesthetists in the *Journal*, I hope you may find space for a few further remarks by way of postscript. Those surgeons who support the retrograde step taken at Addenbrooke's Hospital do not seem to realize that their own art lends itself to division among trained technicians. Might it not be beneficial to the patient if he were under a physician who could prescribe all treatment, treating the patient as a whole and calling in the technicians when indicated? The day of the "hernia nurse," the "whitlow nurse," and the "haemorrhoidal porter" may yet come! I think the real answer is that a person who is doing one job all the time will always be better than one who does it occasionally, or one who is recently qualified and is exploring vast new territories in the continent of medicine and surgery. In a given case the type of anaesthetic to be employed in the best interests of the patient can only be accurately assessed by the physician-anaesthetist; surgeons are apt to be parochial in this matter. If mere technicians are to be employed in surgery or anaesthesia it is an end to progress, and this branch of medical science will remain stationary.

Coined Medical Words

Dr. W. A. BREND writes: I am grateful to Dr. Sutton for pointing out (July 5, p. 38) that hyperphobesis is preferable to hyperphobosis as a term for "excessive fear reaction." I do not, however, care for *φῆκη* (shuddering) as an alternative, since hyperphobesis is more likely to be readily understood and memorized by those already familiar with the significance of the prefix "hyper-" and of the word "phobia" in psychiatry.

The Golden Rule in Reception Areas

The National Baby Welfare Council (29, Gordon Square, W.C.1) has produced a sensible and simply worded leaflet (No. 87, "To Hosts and Guests") which it hopes will help to solve some of the difficulties caused by evacuation. The key phrase of this leaflet is "Give and Take." Supplies may be obtained from the Council at 2s. a hundred. A specimen copy will be sent on receipt of a penny stamp.

Corrigenda

An error occurred in Captain R. E. BURKITT's article "Flat-foot in Recruits" at page 967 of our issue for June 28. In the paragraph dealing with alterations to boots, the phrase "I had a rise of one-quarter of an inch or one-third of an inch put on the under side of the heel and sole of both boots" should have read: "I had a rise of one-quarter of an inch or one-third of an inch put on the inner side, etc."

In Captain WILLIAM E. SMITH's paper on the control of gastric hyperacidity and peptic ulcer published in the *Journal* of July 5 (p. 13) two corrections were received too late owing to delay in the post: (1) Page 13, column 2, line 39—for "reference" read "inference." (2) Page 14, column 1, line 15—for "9" read "10"; and column 2, lines 1 and 8—for "4" read "5."

DEPRESSIVE STATES IN THE SOLDIER

THEIR SYMPTOMS, CAUSATION, AND PROGNOSIS

BY

R. F. TREDGOLD, M.B., B.Ch., D.P.M.

Captain, R.A.M.C.

Among the patients of a military hospital for psychotics the number of cases of depression appeared to be noteworthy. These cases were of many different types, they had been precipitated by a number of causes in various personalities, and their course varied. An attempt was therefore made (i) to differentiate the types; (ii) to analyse the factors in each case and to correlate them if possible; and (iii) to describe the course, and response to treatment, of the various cases.

Differentiation of Types

In 1926 began the considerable controversy in this country on the question of differentiation between psychoses and neuroses, which unfortunately still continues. This had been provoked by Mapother (1926), who stated that the distinction had grown out of practical differences and that he could find no other basis for it. This was hotly contested by many speakers, their protagonist being Ross (1926), who has since defined his views more concisely (1937), stressing the differentiation of anxiety states from depressive psychoses. In point of fact he does not mention depression as a symptom occurring in an anxiety state, but his distinction of the latter from the depressive psychosis is based on the extent of its dependence on environment, as well as on the absence of retardation and presence of insight.

Gillespie (1929) set up a group of neurotic depressions, separated from the psychotic in their greater reactivity—that is, the greater dependence of their affect on conscious factors, internal or external. He also gave a list of criteria suggested for the distinction of neuroses from psychoses (Gillespie, 1930). Yellowlees (1930) also held these views, basing his distinction on the patient's possession of insight.

Rogerson (1940) has based on the above views a classification into psychoses and neuroses, each again subdivided into anxiety and depressive states, the distinction—the integrity of the rationalizing power of the mind—thus resting on a study of the extent of the dependence of the mood-change on external reality and conscious strivings. He holds also that in a psychotic a defence mechanism operates in a far more wholesale way than in a neurotic.

It may here be interesting to note that many of this school base their sharp distinction on *one* criterion—but this criterion is itself a matter of degree. Thus Rogerson diagnosed the psychotic type by the far more wholesale appearance of a defence mechanism, and Yellowlees by the possession of insight, a quality whose assessment (as Curran points out) Lewis (1934b) has shown to be extremely difficult, while Gillespie's most important criterion was of comparatively less reactivity. It would, however, seem more helpful to look for a distinction, if any, in the mechanism of the reaction. Thus it might be held that neurotic depression is an exaggeration of a normal reaction—that is, an attribution of failure to insurmountable difficulties—while the psychotic depression is com-

pletely abnormal, being, in its admission of total failure, biologically dangerous.

The basis of such a distinction was thus held by the authorities quoted as resting on psychopathology, and its use was justified in that it indicated also a complete distinction of treatment and prognosis, as will be mentioned later. Completely opposite views have, however, been given in classic phrases by Mapother and Lewis (1937), who, speaking generally, stated that distinction between neurosis and psychosis is at times convenient but without substance. Lewis (1934a) condemns a sharp distinction between depressive states as not found in Nature and of no help to thought and action, and stresses that, like every other illness, depression is the result of environment working on the organism: there will be a great number of possible combinations according to the individual's inherited endowment and training, and the particular constellation of environmental forces. Applied to his cases Gillespie's criteria gave contradictory results. Lewis's view was supported by Curran (1937), who also attacked the criteria of distinction suggested by Gillespie, and in various cases showed an entire absence of correlation. He proposed that the types of depression should be regarded as a graded sequence. He also attacked the sharp distinction in recommended treatment. Symonds (1939) considered the difference in types to be merely one of degree.

Grouping of Cases

Of 274 consecutive cases admitted to the hospital in the first six months 70 were selected as "depressions." This diagnosis was made on the criterion of "anyone who was unhappy and ill with his unhappiness" without any other significant illness to cause this (Lewis, 1938). The cases were first studied from a clinical standpoint; it appeared that they could be separated into several types entirely from overt symptoms, and it must be emphasized that not until they had been so grouped was their psychopathology considered. Since the symptoms varied during the patient's progress, the most acute phase during their stay in hospital was taken to determine the group. The cases may be classified as follows:

1. *Agitated Melancholia*.—The symptoms were acute misery, apprehension at times amounting to terror, delusions and hallucinations of persecution, and self-reproach. There were occasional periods of calm, which usually ended abruptly. Suicidal attempts were common. These patients showed a complete lack of insight or co-operation.

2. (a) *Anxious*; (b) *Hypochondriacal*.—These patients showed depression accompanied by preoccupation of (a) disaster, or (b) bodily ailment, respectively. Though lacking in self-confidence, they possessed some self-control and could respond to reassurance. There was in some cases a knowledge that their worries were probably exaggerated. The more acute cases of both these subgroups were practically indistinguishable from the milder ones in Group 1.

3. *Emotional*.—Symptoms in this group were a deeper depression with marked emotional instability, sometimes repetition and retardation, with feelings of unworthiness and disaster which in

general the patient realized to be irrational but were none the less distressing. These remains of insight were not, however, associated with any power of co-operation.

4.—This group may be regarded as midway between Groups 2 and 5, anxiety being on the decrease but retardation the reverse.

5. *Retarded*.—Retardation was here pronounced, and in some cases amounted to stupor. No agitation or repetition occurred, and there was little emotional instability. The patient often expressed himself as desiring merely to lie curled up in bed and to be left alone. Suicidal attempts had frequently been made before admission. Co-operation varied with the degree of retardation.

6. *Recovering (?)*.—The last group consisted of five patients whose symptoms had disappeared to a great extent by the time of admission but who had attempted suicide while acutely depressed; their history was, however, not adequate enough to decide into which of the above groups they should fall.

There are thus a number of cases ranging from the acutely agitated to the acutely retarded, which, though they have here been subdivided, could accurately be described as a sequence. Groups 1, 2, 4, and 5 present a more or less regular sequence; Group 3, though placed

SPECIFIC TREATMENT.—S = Somnifaine. C = Cardiazol.

between Groups 1 and 5, may be regarded as a little off the direct line, being characterized by emotional instability (with little anxiety).

Once these cases had been grouped on clinical grounds their possession of insight and their response to environment were noted; the exact assessment of each of these factors in any individual was extremely difficult, but an attempt was made to represent their relative strength by symbols as in Table I, Column 3. It was also noted whether the patient placed the blame for his depression on his environment or on himself.

If these were regarded as the criteria by which to distinguish psychosis from neurosis the more acute clinical states either of anxiety or of retardation could be grouped as psychoses, and the milder as neuroses. However, the contention is here put forward that efforts at such distinction are both false and misleading, and that it is correct to regard the cases as a graded sequence

Transition

Transition from one condition to the other seems to have evoked curiously little remark in recent literature. Rogerson, moreover, quotes Ross's figures of the follow-up of 1,043 cases of neurosis discharged from the Cassel Institute (and of which only 5% later developed psychosis) as evidence that a distinction between the two types existed. In any case, there seems no particular reason why a mild type of illness should be more severe on recurrence. A similar follow-up of recovered psychotics would be interesting. Recently, however, Symonds (1941) commented on the frequency of diurnal variations from "neurotic" to "psychotic" type.

A study of the individual cases in our series showed that a number of those convalescing passed from a condition undoubtedly psychotic to one that was neurotic (by the above criteria), and a number of those relapsing did the reverse. Thus Case 6 on admission was agitated, inaccessible, and had repeated delusions of impending disaster, coupled with auditory hallucinations; his delusions faded as he recovered, but he showed some anxiety and repetition, and increasing insight and co-operation. In contrast; patient No. 5—who when admitted was mildly anxious and lacking in self-confidence, who worried over real financial matters and lack of Army promotion, but was moderately co-operative—relapsed into a condition of acute terror, with vivid delusions of persecution by Germans and a complete lack of insight or co-operation. Here the rapid transition of such cases certainly supports the hypothesis that the difference between the psychotic and the neurotic is merely one of degree.

Factors Influencing the Onset

Probable causative factors were next studied, although it must be admitted that several cases showed very inadequate personal and family history. The following were the factors considered:

A. Internal.—(1) Family history of any psychopathic weakness. (2) Previous personality.—The cases were here grouped under three headings: (a) mental defectives; (b) psychopathic types, including those who had (i) suffered always from ideas of inferiority, hysterical reaction, or had been of a worrying disposition, or (ii) had had previous attacks of depression (which may or may not have led them into a mental hospital); (c) those previously apparently entirely normal.

B. External.—(3) Long-standing factors.—(4) Sudden factors.—Factors 3 and 4 were each subdivided into Physical Illness; Family Worry; Bombardment; and Incompatibility with Military Discipline. Where the mere fact of enlistment seemed the only cause, this was noted. These factors were major, such as bereavement, infidelity of wife, etc., or minor—certainly an arbitrary division.

Table I shows the incidence of these factors in each group (Column 1); Tables IIa and IIb summarize them.

TABLE IIa.—Internal Factors (70 Cases)

Previously normal	9
Psychopathic	24
Inferiority	7
Worrying	15
Hysterics	2
Depression (5 previously certified)	16
Mental defectives	21

A psychopathic family history was traced in 14 patients (of whom 6 were "chronic worriers").

TABLE IIb.—External Factors

	Total	Long-standing		Sudden	
		Major	Minor	Major	Minor
Bombardment	19	16	1	2	—
Family troubles	22	4	1	9	—
Incompatibility to discipline	15	1	2	—	12
Enlistment	13	—	—	—	13
Physical	9	—	2	—	7

NOTE.—In 17 cases more than one external factor was evident; in 2 of these both major.

These conclusions may be drawn from Tables IIa and IIb in connexion with Table I: (1) No particular correlation could be traced between any type of previous personality and any clinical group. (2) Out of 18 cases in the anxious and hypochondriacal group 9 had previously been subjected to severe bombardment at Dunkirk and had later broken down, in response at most to a minor precipitating factor; one other case had suffered recent bombardment. (3) Apart from those cases no particular correlation could be traced between any external factor and any clinical type.

TABLE III.—Analysis of Cases, showing Incidence of Minor and Major Factors

	Major	Minor only	Nil Ascertained	Total Cases
Normal	8	1	—	9
Psychopathic	10	10	4	24
Depression	4	8	4	16
M.D.	8	12	1	21

NOTE.—In some cases several minor factors were together; these are shown under "Minor only."

But here again no correlation could be found (see Table IIb) between these and any clinical type. It is, however, noteworthy that in fact, as might be expected, the proportion of major to minor factors is far greater in the previously normal than in psychopathics and mental defectives, especially in previous depressives. A recent publication by Curran and Mallinson (1941) has shown that no clear-cut clinical distinction could be found between "endogenous" and "reactive" (so-called) cases of depression in the Navy, and that the cases formed a graded sequence, being borderline. They hold, nevertheless, that there are, at the two extremes of the sequence, distinct clinical types—namely: (1) the "endogenous," which might or might not have been precipitated by external stress, mainly characterized by certain typical symptoms such as retardation, ideas of reference and self-reproach, and a "depressive content"; and (2) the "reactive," mainly characterized by the dependence of the illness upon traumatic experiences which gave rise to a "topical content," but not showing the typical "endogenous" symptoms mentioned above with the same frequency or intensity. In the former they find 25 adequate factors and in the latter 48, thus suggesting that the external factors produce a clinical type distinct from the internal.

Such a suggestion is not supported by the figures of this series, in which, it must be noted, the proportion of previously normal individuals is much lower; for clinically similar cases resulted from a completely different set of interacting factors. It seems only possible to conclude

that any state of depression is the result of the interaction of external factors upon a personality; and that, so far, there is not enough evidence to predict the occurrence of any particular syndrome in any particular individual.

Treatment

1. *Rest*.—The patients were kept in bed for at least twenty-four hours, practically all for forty-eight hours, and some for a week. During this time the question of future treatment and of narcosis therapy was considered. The majority of the patients, however, were those whose progress appeared satisfactory; they were got up and given in the first place light jobs, usually in the ward, requiring little concentration, responsibility, or perseverance. Their existence was ruled by a fairly strict routine time-table; it included regular fresh air and adequate meals. Gradually their occupation was made more interesting and more vigorous, and so far as possible in tune with their own hobbies or occupations. This, of course, was not always feasible, and rug and basket making, digging, and weaving proved valuable substitutes, with the help of much-varied physical training and entertainment such as cinemas and organized games.

2. *General Psychotherapy*.—This consisted in giving individual encouragement and reassurance, and later included a series of talks, leading the patient to adjust his personality to cope with his difficulties so far as was possible and stressing the fact that he had passed through an illness caused, like any other, by physical factors. There can, however, be little doubt that a number of patients for whom no individual attention was then available recovered as completely, though perhaps more slowly.

3. *Prolonged Narcosis*.—Those patients whose progress appeared unsatisfactory after a few days' observation or who suffered acute anxiety were recommended prolonged narcosis. Thus it was advocated for all members of Group 1 and several of Groups 2, 3, and 5. For some of such cases, however, it was not available by reason of administrative difficulties in the early days of the hospital. Thus a series of clinically similar controls is provided. In all, 19 cases were treated. The technique adopted was that described by Ström-Olsen (1933, 1934), using somnifaine, insulin, and glucose; or that suggested by Palmer (1937), using somnifaine and paraldehyde. Average daily sleep varied from twelve to eighteen hours, and was in most cases over fifteen and a half hours. In cases other than Group 1 it can scarcely be said that narcosis improved the number of recoveries, for the rate was exceedingly high in any event, but those treated with narcosis did appear to recover more quickly. In cases of Group 1, however, the results were extremely interesting, and may be set out thus:

TABLE IV.—Results in Group 1

Case No.	Narcosis	Progress	Subsequently	Further treatment	Progress	Result
1	No	Unchanged	Remained so	Nil	—	M.H.
2	Yes	Improved	Relapsed	Narcosis	Slightly improved	H.
3	..	Improved	..	Nil	—	H.
4	..	Slightly improved	..	Nil	—	M.H.
5	..	Improved	..	Insulin	Improving	Not yet discharged
6	Cardiazol	Recovered	To civil life
7	Insulin	Improving	Not yet discharged
8	Remained well	To civil life

There are as yet insufficient data on the question of relapse; but it must be stressed that at least two patients, after apparent recovery, became far worse than on admission, showing an acute agitation, with marked delusions of persecution.

4. *Shock Therapy*.—This was recommended for the cases of relapse and also for the case that was unchanged after narcosis, as well as for one which showed only very slight improvement after some weeks. Owing to relatives' objections, however, it could be given to only 4 cases, 2 of which received cardiazol and 2 insulin. Considering first those in Group 1, one which was given cardiazol was discharged recovered. Two given insulin are steadily improving but are not yet discharged. The three which were given no further treatment, as well as Case 3, which was given further somnifaine, were, as persons of unsound mind, only able to be sent either to their relatives or direct to civil mental hospitals—two are known to be in the latter. The eighth case in Group 1, as was seen, recovered without narcosis. The only other case given cardiazol recovered.

Prognosis

Prognosis must be regarded as very good, apart from the cases of agitated depression (Group 1). For of 62, only 2 were classified as "unfit for civil employment," and 3 others as "fit only for sheltered employment." Of Group 1, however, 4 showed practically no improvement, while 4 did improve. The dependence of recovery on adequate treatment (if necessary, shock) appears probable. Of the above-quoted 9 failures 5 were mental defectives. The follow-up of such cases is not yet adequate, but an effort is being made to keep in touch with them: so far none marked "fit" are known to have relapsed—the longest time after discharge, however, is only five months. It will be noted that no men returned to duty, whereas 57 went back to normal civil employment. This result is due to the instructions of medical boards, which have insisted till recently on the elimination of all those at any time diagnosed as depressive cases, discussion of which is beyond the scope of this paper.

Summary

The incidence (25.5%) of cases diagnosed as depression in admissions to a military mental hospital is noted.

These were classified into groups entirely on clinical grounds: no sharp differentiation could be observed between such groups, which could be regarded rather as a graded sequence of cases.

An analysis is made of various factors—predisposing and precipitating. No correlation between such factors and any one clinical syndrome could be found, with the exception of a syndrome following some time after severe bombardment. The occurrence of any type of depression does, however, appear to be the result of the interaction of external and internal factors.

The treatment is described.

The prognosis is considered good—59 cases out of 70 making a complete clinical recovery.

I am extremely grateful to Lieut.-Colonel J. I. Russell for permission to publish these cases and also to him and to Major H. A. Palmer for much help and interest in the discussion of the material.

THE CLASSIFICATION OF CASES OF ALBUMINURIA

BY

ALEXANDER LYALL, M.A., M.D., F.R.C.P.

Lecturer in Clinical Chemistry, University of Aberdeen

The careful medical examination of large numbers of entrants to the Services has provided a new opportunity for the study of groups of young adults in whose urine albumin is discovered on routine tests. Analysis of the data collected in the present work has substantiated the figures of previous investigations. In addition, since examination was possible in more complete detail than in earlier observations of this kind, it has been shown that subacute nephritis is relatively common as a sequel of transitory respiratory infections and that early types of chronic nephritis exist in which the condition is unsuspected symptomatically and in which the disease may progress until the later stages become manifest.

Previous Work on Classification

The basis of classification of cases of albuminuria was established during the war period 1914-18. MacLean (1919) investigated 50,000 soldiers in training and observed an incidence of albuminuria of 5.8%: in 2.8% the amount of albumin passed in the urine was large, and in 1.1% it was accompanied by an abnormal urinary deposit showing hyaline and epithelial casts and occasionally red blood cells. MacLean concluded that 1.1% of soldiers under training showed some degree of renal damage or nephritis. Similar investigations amongst untrained men suggested that these renal changes were not caused by training and that men showing such changes were capable of the strain of vigorous military preparation. From later work on trench nephritis MacLean concluded that the incidence of albuminuria had no influence on the occurrence of that disease; of 161 cases of trench nephritis among the group of 50,000 men originally examined, only 28 had been albuminuric and only 15 had shown casts in the urinary sediment. This reasoning would be correct only if exposure to the infective agent of trench nephritis were equally distributed.

Although the intervening years of peace added but scanty information to the data, various workers have commented on MacLean's statistics and conclusions. Gulland (1927) analysed data collected for insurance work, and was of the opinion that albumin in the urine accompanied by epithelial casts indicated a desquamative catarrh of the kidneys, which might be trifling or serious, temporary or permanent. He believed that slight degrees of nephritis were more common than was usually thought to be the case. In many instances such mild nephritis was associated with upper respiratory infections. That author was not impressed by the value of renal function tests in cases of mild nephritis; he felt that to accept the view that only renal efficiency tests gave evidence of defective kidneys might be misleading. Fox (1921) also discussed adolescent albuminuria in relation to life insurance and described 20 such cases which satisfied his criteria for diagnosis and which had been observed for upwards of twenty-five years. Five deaths had occurred in this series, but none from renal diseases. Diehl and McKinlay (1932) examined the urine of 20,000 students who entered the University of Minnesota from 1921 to 1930, and found albumin present in 1,065 samples (5.3%). Persistent albuminuria was observed in 118 students (0.6%), and 65 (0.3%) showed evidence of nephritis. Of 606 students in whom albuminuria was discovered, 404 had no

albumin in the urine at later examinations. This group the authors called transient albuminuria. Ashburn (1928) examined 1,115 Army cadets from two to six times during the years 1924-6. Albumin was found in the urine of 16%, with hyaline casts in 41 instances, granular casts in 14, and red blood cells in 15.

The material investigated in the present work consisted of 110 men who showed albuminuria on more than one occasion when examined for recruitment to the Services. This incidence occurred in the examination of 20,000 men (0.55%). The method of investigation adopted was as follows.

Investigation of Cases of Albuminuria

A sample of oxalated blood and a sample of urine were collected when the patient reported. A set of three bottles with suitable labels and a bottle containing 15 grammes of urea in 100 c.cm. of water were provided, along with the following instructions:

INSTRUCTIONS

Have nothing to eat or drink after 8 o'clock to-night.
Go to bed at 9 p.m. and pass water at 10.30 p.m.
At 7 a.m. pass urine and keep in Bottle 1. Take draught (15 grammes of urea).
At 8 a.m. pass urine and keep in Bottle 2.
At 9 a.m. pass urine and keep in Bottle 3.
Report to laboratory at 9.30 a.m.
Have nothing to eat or drink in the morning.

A further specimen of urine, collected when the patient reported, provided a sample after exercise.

The blood-urea value was determined and the urea-concentration test was performed. All samples of urine were tested for albumin, and microscopical examinations of the centrifuge deposits of the single sample of urine and of the first and last samples of the urea-concentration test were made. From the data thus obtained, from the relevant history, and from the examination of the patient it was possible in practically all instances to decide whether the case was one of orthostatic albuminuria or whether some degree of renal pathology was present.

Classification

Analysis of the data collected in this study showed that patients with albuminuria could be divided into five main groups, as shown in Table I.

TABLE I (110 Cases)

A. Orthostatic albuminuria	31
B. Albuminuria without evidence of nephritis	22
C. Subacute nephritis	14
D. Chronic or subchronic nephritis	31
E. Urinary infections; haematuria; various	12

Although statistics are of relatively little value in arriving at a decision in the individual case, these figures show that roughly 30% of cases of incidental albuminuria can be classified as orthostatic in type. On the other hand, 40% are found on investigation to reveal some evidence of renal pathology. In Table II typical instances of Groups A, B, C, and D are collected for comparison. The gradation in abnormality, in ability to concentrate urea, in the amount of albumin, in the character of the urinary deposit, and in blood pressure is demonstrated in this table.

Orthostatic Albuminuria

This term has been chosen for Group A in preference to adolescent albuminuria as the age group (18-35) is beyond the period of adolescence, and also in preference to benign

TABLE II.—*Typical Cases of Groups A, B, C, and D*

Case No.	Age	Blood Urea	Concentration Test				Albumin				Deposit				B.P.	Remarks

albuminuria, a term which would include some cases in Group B. For inclusion in this classification the following criteria are essential:

- Albuminuria is transient and the urine passed during rest is free of albumin.
- The urinary deposit shows no pus cells, red blood cells, or renal casts.
- The urea concentration reaches over 3% and the blood-urea value is normal.
- There is no history of illness, particularly a recent illness, which might result in nephritis.
- The blood pressure is normal and there are no clinical evidences of nephritis or anatomical abnormalities of the urinary tract.

The amount of albumin present in the urine during activity varies from traces to considerable amounts (up to 0.2% Esbach). In 18 out of 32 cases the quantity of albumin seen at the first examination was large. In samples of urine collected next day, only traces of albumin were found, except in one case. There is suggestive evidence that the amount of albumin passed is increased with the temporary rise in blood pressure, which often occurs during medical examinations as one manifestation of adrenal stimulation. In the centrifuge deposit an occasional hyaline or granular cast seen in the first sample of urine may be neglected. This happened in six instances in this group. Calcium oxalate crystals occur frequently, but unless accompanied by red blood cells are not of pathological significance.

The aetiology of the condition is still in doubt. One or more of a number of factors, including constitutional diathesis, lordosis, and pressure on the left renal vein, have been postulated as causative by various workers. In the present group five individuals had had scarlet fever between the ages of 9 and 14 years, two had had diphtheria, and one had had typhoid fever. The influence of previous fevers is still in doubt. Russell (1925) called attention to the fact that orthostatic albuminuria was often a phase of scarlatinal or diphtheritic nephritis and possibly of other forms of the disease, the sequence being: constant albuminuria—orthostatic albuminuria—none. Diehl and McKinlay (1932), on the other hand, could find no statistical significance in the incidence of precursory diseases. With this in mind, it should be emphasized that, although no evidence of renal involvement can be elicited, the diagnosis of orthostatic albuminuria is nevertheless one of personal opinion and not of absolute certainty. But in view of the accumulated evidence regarding the innocuous nature of the condition, men classed as cases of orthostatic albuminuria can be accepted for service in the Forces in the higher grades and frequently in Grade I.

Albuminuria without Evidence of Nephritis

The cases in this group could not be classed as benign albuminuria or orthostatic albuminuria. In each instance some feature was present which raised doubt, although there was not enough evidence to be certain of interference with renal function. The urea concentration was below normal in six instances, with maximum concentration between 2.2 and 2.9% urea. In the rest the urea concentration reached normal figures. Albuminuria was persistent in eight cases even at rest. In the others the resting sample of urine was free of albumin. Occasional polyuria was found in two patients along with reduced figures for urea concentration but without other abnormality in findings. In the urinary centrifuge deposits an occasional granular or hyaline cast was present in five, a few red blood cells in two, and pus cells in six instances. The blood pressure was above normal in five cases, ranging up to 160/80; in this instance the resting blood pressure was 142/80, and in another the pressure was 154/90 during activity and fell to 120/74 during rest. Only three patients in the group had suffered from scarlet fever, in one instance in conjunction with diphtheria and in another with rheumatic fever.

In this group the individual case is difficult to evaluate. Such cases cannot be classified as orthostatic or benign albuminuria, nor, on the other hand, can they be placed among the nephritides, since there is no actual evidence of renal lesion. In all instances the grading suggested was II or III. The following is a description of a typical case.

A painter aged 32, married, with two children, this patient had never had scarlet fever, diphtheria, or other illness, and had never been off work. There had been oedema, dysuria, polyuria, or nocturia. He had had a septic finger in January, 1940, and an injury to the nose and displacement of septum at the age of 20. The pulse rate was 64 and blood pressure 130/80, and the heart sounds were good and pure. No abnormality was found on examination of the chest and abdomen. The kidneys, spleen, and liver were not palpable. The pupils were central and equal, and reacted normally. The reflexes were normal. The blood urea was 28 mg. per 100 c.cm. A urea-concentration test with 15 grammes of urea gave:

1. Fasting urine	2.9% urea	Albumin trace
2. At 1 hour	2.8% "	" +
3. " 2 hours	2.9% "	" +
4. " 3 "	2.6% "	" +

The centrifuge deposits in Sample 1 showed numerous calcium oxalate crystals. No pus cells, red blood cells, or casts were found. The deposit in Sample 4 showed an occasional leucocyte but no casts, red blood cells, or crystals. This case was summed up as persistent albuminuria with urea-concentration values rather below standard, but without evidence of nephritis.

Subacute Nephritis

This group included 14 individuals between the ages of 18 and 37 who showed either clinical or pathological evidences of recent nephritis. Various factors suggested the conclusion that the lesion present was of recent origin and could be classified as acute or subacute nephritis. In all these cases, with two exceptions, there was a history of illness, including sore throats, severe chills, influenza, and cellulitis, within the previous two months. Scarlet fever had not been present in any instance. In two cases oedema of the hands and puffiness of the face were found. The blood-urea value was increased to between 40 and 50 mg. per 100 c.cm. in four instances. The albumin in the urine was considerable in amount (up to 0.3% Esbach), and was constantly present. The urea-concentration tests gave maximum values of over 3% in six cases and of less than 2.5% in one case only. The urinary deposit contained epithelial casts as evidence of acute renal desquamation in all but two instances. Granular casts were also frequently found, and red blood cells were seen in all except two. The blood pressure was raised to between 140 and 150 systolic in five patients; the diastolic blood pressure was never above 88 mm. Hg.

Such men are obviously unsuitable for recruitment. In most instances, if the lesion seemed very recent, a further review of the condition was suggested after an interval of three months. The opportunity occurred to examine two members of this group several months later.

In the first of these two cases the man passed at 6 p.m. a sample of urine which contained much albumin. The centrifuge deposit showed red blood cells and epithelial and granular casts. The blood-urea value was 50 mg. per 100 c.cm. A urea-concentration test next day gave 2.2, 3.0, 3.0, 3.0% urea. All samples of urine contained much albumin, and the deposit showed considerable numbers of red blood cells and epithelial casts. There had been frequent colds and influenza, but the man had not been off work recently. The pulse rate was 68 and the blood pressure 128/70. The heart sounds were good, but a systolic murmur was present at the mitral and pulmonic areas. The throat was congested and the left tonsil infected. Conjunctivitis was present and the face was slightly puffy. The condition was classed as mild subacute nephritis. The case was reviewed three months later, when a urea-concentration test gave 2.4, 2.5, 2.6, and 2.5% urea. All samples of urine contained albumin, and the deposit from several of them showed epithelial casts, blood casts, and red blood cells. The blood urea was now 30 mg. per 100 c.cm. and the blood pressure 128/78. In this instance the condition was progressing to subchronic nephritis.

In the second case, at 4.30 p.m., the man passed urine which contained a large amount of albumin. The deposit showed a few hyaline casts but no pus, blood cells, or crystals. The blood urea was 30 mg. per 100 c.cm. A urea-concentration test next day gave 2.45, 2.3, 2.6, 2.7% urea. All samples of urine contained much albumin, and the centrifuge deposit showed a number of casts, partly epithelial and partly granular, and a few red blood cells. This man had had tonsillitis frequently until four years previously, but had never had scarlet fever. He had been chilled and wet a few nights previously on fire-watching duty and developed a headache and lumbago afterwards. The pulse rate was 100 and blood pressure 150/86; there was a systolic murmur at the pulmonary area and a slight puffiness of the face. The condition was classed as mild subacute nephritis which might resolve. The patient was seen three months later in hospital. His appetite was good and the bowels were regular. He admitted occasional slight frequency of urination, but no blood had been passed. There was no visual trouble, numbness, or anaesthesia, and there had been no giddiness or headaches or vomiting, no cough or dyspnoea. Palpitation on exertion had been noticed, and a tendency to sweat easily. He had had measles as a child, but not scarlet fever or diphtheria. He had had several attacks of tonsillitis, the last three years earlier. He had never had rheumatic fever, but had had lumbago four months previously. His parents and four sisters were alive and

well. He had one child, one month old. Examination showed him to be a well-developed and well-nourished though edentulous man. There was no anaemia. His throat was healthy and his tongue clean. Pulsation was visible in the suprasternal notch. The thyroid gland was not enlarged. The pulse rate was 92 and the blood pressure 140/80 to 150/68. The heart sounds were good, but there was a systolic murmur at the mitral area. The heart was not enlarged. Nothing abnormal was found on examination of the chest, abdomen, reflexes, or cranial nerves.

The urine had a specific gravity of 1008 to 1017, and contained from 0.8 to 0.9 gramme of albumin per litre continually. A urea-concentration test showed: fasting, 2.45% of urea; at one hour, 2.3%; at two hours, 2.6%; and at three hours, 2.7%. The blood urea amounted to 30 mg. and plasma proteins to 6.7 grammes per 100 c.cm. The urine deposit contained numbers of hyaline and some granular and epithelial casts, together with a number of red blood cells. Volhard's water-excretion test gave a specific gravity between 1005 and 1032, and 36 oz. was excreted in three hours. Radiographs failed to reveal any urinary calculus.

Examination of the blood showed 5,120,000 red cells, 7,100 leucocytes, and 90% haemoglobin. The basal metabolic rate was +5%, and the Wassermann reaction was negative.

It is evident from the occurrence of such cases that milder degrees of subacute nephritis may occur in men who otherwise appear healthy and do not seek medical advice or remain off work. The end-result of such attacks is not known, but in the two instances quoted the disease progressed to a subchronic stage.

Chronic or Subchronic Nephritis

This group consisted of 31 individuals, of whom 26 were between the ages of 20 and 35 years, 18 and 47 being the age limits. All were found to have continuous albuminuria, often of considerable degree. The blood urea varied between 20 and 52 mg. per 100 c.cm., with values over 40 mg. in 7 instances. The urea-concentration factor lay below 70 in 11 instances; 7 of these were below 50. The urea-concentration test showed maximum values under 3% in 17; in 13 the maximum values were below 2.1%. In all cases fairly numerous casts, usually hyaline and granular in type, were found repeatedly in the centrifuge deposits of the urine. Red blood cells were present in all except three instances. The blood pressure showed systolic readings of 140 mm. Hg or above in 15 patients, of whom 7 showed readings over 150, the highest being 192. Diastolic pressures were raised to between 90 and 100 mm. Hg in 7 cases. In 10 patients symptoms referable to the presence of chronic renal diseases were elicited on question only. Two men complained of headache, two of occasional frequency of micturition, two of both these symptoms, and two of backache and pain in the renal region. Positive signs referable to renal disease were few. In one instance slight oedema of the face and arms was present, and one patient had dyspnoea on effort; two were much under weight, and one had aortic incompetence. Two were anaemic, and one showed polycythaemia. There was no history of any illness of aetiological significance in eight of these men. Only three men gave a history of having had scarlet fever before the age of 10 years, and one had had scarlet fever two years earlier. In three there was a history of nephritis 2 years, 11 years, and 12 years earlier, and one patient, whose blood urea was 52 mg. per 100 c.cm. and whose blood pressure was 164/94, was known to have had albuminuria 11 years previously. Five men had had recurrent attacks of tonsillitis, and nasopharyngeal infections were actually present in three instances. Other previous illnesses included septic hands (2), erysipelas (1), compound fracture of tibia (1), rheumatic fever (1), and exophthalmic goitre (1). There was very little evidence of urinary infection, and cystitis was

present in only one case. All of these men (except two) were employed, and they comprised labourers (5), millworkers (2); fishermen (2), a blacksmith, a plasterer, a slater, as well as others following less strenuous occupations such as clerk, cinema operator, and collector. Two individuals in this group were examined twice at an interval of a year, and one was observed later in hospital. The records of three of these cases give some indication of prognosis in this group.

A millworker aged 35, married, with nine children, this man had never had scarlet fever, diphtheria, or typhoid fever, although he had been in hospital in 1923 for observation as a doubtful typhoid carrier. Five years earlier he had served in the Territorial Army and had done strenuous training. He had no headaches, polyuria, or oedema; was thirsty occasionally, but only when sweating at work in a hot atmosphere; had occasional indigestion; and was constipated. He did not admit any history of venereal disease. Examination showed a rather thin, pale, undernourished, edentulous man. The pulse rate was 70, regular, and the blood pressure 128/70. The apex beat was in the nipple line. A systolic murmur was present in the mitral area and the second pulmonic sound was accentuated. Examination of the lungs and abdomen revealed no abnormality. The reflexes were normal, the pupils reacted normally, and the throat was clean. The blood-urea value was 46 mg. per 100 c.cm. A urea-concentration test gave 1.8, 2.4, and 2.8% urea, and a urea-concentration factor of 1/40. All samples of urine passed contained from 0.1 to 0.2% of albumin, and the centrifuge deposit showed a number of granular and epithelial casts with numerous red blood cells. This man was seen again 16 months later. He had been well in the interval, but had been unemployed. He noticed that he had to get up to pass water, usually about 4 a.m. He had no headaches or dyspnoea, and took a cheerful view of himself and of his environment. The blood urea was now 40 mg. per 100 c.cm. A urea-concentration test gave figures of 0.8, 1.15, 1.1, and 1.6% urea and a urea-concentration factor of 1/20. All samples of urine contained much albumin (0.3%), and the centrifuge deposit showed numerous granular casts, some epithelial casts, and numerous red blood cells. The pulse rate was 70 and the blood pressure 130/70. The apex beat was outside the nipple line, and systolic murmurs were present over the mitral, pulmonic, and aortic areas, with a suggestion of a diastolic murmur down the left side of the sternum. This evidence shows a progressive case of chronic interstitial nephritis with gradual failure of renal function.

A slater aged 34, married, with one child, had never had any major illness or scarlet fever or sore throats, but had sustained a compound fracture of the right tibia at football thirteen years earlier. This was reduced and plated in hospital, and the patient played football again in later seasons. There had been no headaches, polyuria, or oedema, and his eyesight was good. He looked a healthy well-built man. The pulse rate was 54, the heart sounds were good and pure, and the blood pressure was 120/80. Examination of the chest and abdomen showed no abnormality. The liver, spleen, and kidneys were not palpable. The upper jaw contained three carious molars. The throat was clean. The reflexes were normal and the pupils reacted normally. The blood urea was 32 mg. per 100 c.cm. A urea-concentration test showed 2.3, 2.6, 2.8, and 2.9% urea, with a urea-concentration factor of 1/70. All samples of urine contained albumin, and the urinary deposits showed numerous granular casts, a few epithelial casts, some red blood cells and calcium oxalate crystals. Twelve months later the man felt well, had been working continually, and had no untoward symptoms. The pulse rate was 68 and the blood pressure 142/90. A general examination gave normal findings. A urea-concentration test showed 2.1, 2.4, 2.5, and 2.8% urea. The amount of albumin in the urine was increased and it was found in all samples. The centrifuge deposit contained numerous granular and hyaline casts, a few red blood cells, but no crystals or pus. This case shows chronic nephritis, which has remained almost stationary during one year.

An unemployed storeman aged 24, this patient had never had scarlet fever, sore throats, polyuria, or swelling of face or hands. His appetite was good and his bowels were regular. The pulse rate was 60 and the blood pressure 138/90. The heart sounds

were good and pure, the reflexes were normal, and the pupils reacted normally. The kidneys, liver, and spleen were not enlarged to palpation. The upper teeth were bad and the upper incisors had been extracted, but the throat was clean. A sample of urine passed at 4.30 p.m. on March 6, 1940, contained a large amount of albumin, and the centrifuge deposit showed a number of hyaline, granular, and epithelial casts, some pus cells, and a few red blood cells. The blood-urea value was 29 mg. per 100 c.cm. and the urea-concentration factor 1/34. A urea-concentration test gave 1.0, 1.2, 1.4, and 1.9% urea. All samples of urine contained much albumin, and the centrifuge deposit was similar to that described above. On observation in hospital two months later the blood pressure was found to be 145/95, but it fell to 108/68 after rest in bed for several days. The specific gravity of the urine reached a maximum of 1018 on restricted fluids and urea-concentration tests. Intravenous pyelography with uroselectan showed poor concentration and delayed excretion. The right renal pelvis and ureter were normal, but opacity was not sufficient for an opinion on the left kidney and ureter to be formed. Albuminuria persisted for ten days while he was in bed, and the urinary deposits continued to show granular casts. A diagnosis of chronic interstitial nephritis was made.

The recognition of this group of men with chronic nephritis of varying degree makes it evident that an early type of renal disease exists, often without any defined aetiology and usually without symptoms at this stage of the disease. The further history of such cases is not known, and no information is available on which a prognosis can be based. The disease may progress with rapidity until symptoms of renal failure or cardiovascular insufficiency become obvious to the patient and to the medical attendant, or progress may be delayed for a number of years. It seems reasonably certain that this group forms part of the mosaic in the earlier aetiology of chronic nephritis and constitutes the reservoir from which patients are admitted from time to time to the wards of the general hospitals with the fully developed picture of advanced renal failure, terminating in uraemia. It is doubtful whether at this stage any good purpose can be served by hospital treatment or treatment by any strict dietetic or other regime, and invalidism is to be avoided.

The value of such an investigation as the present one would be greatly enhanced by inclusion of the collected statistics from other areas in the country. This is particularly the case since the patients have been more fully investigated than in MacLean's series during the war of 1914-18 and since the opportunity exists to make follow-up observations on many of these cases at a later date. In local areas with regional hospital administration it should not be impossible to check such admissions in future years.

Urinary Infections; Various

Group E consisted of 12 men who were found to have albumin and whose urine on microscopical examination revealed in addition haematuria or pyuria. In two cases nephrectomy had been previously performed for tuberculosis of the right kidney and tumour of the left kidney. In two cases renal calculi had been passed. One man had had haematuria two years earlier, and the remainder had had urinary infections with much pus in the urinary deposit.

It is of considerable value to review the importance placed on interpretation of the various findings obtained in investigating this group of cases from the renal aspect.

Albuminuria.—If albuminuria is transient, and particularly if the resting sample of urine is free of albumin, the classification is probably albuminuria of the orthostatic type. The amount of albumin present in an isolated sample of urine is no guide to classification, since in men with orthostatic albuminuria such samples may contain much albumin. If albuminuria is persistent the patient belongs to the other groups. In most cases of nephritis albumin continues to be excreted in large amounts.

The Urinary Deposit.—If the centrifuge deposit shows no pus cells, red blood cells, casts, or crystals on several examinations the albuminuria, with few exceptions, is of the orthostatic type if transitory and of the benign type if persistent. An occasional cast of the hyaline or granular type may be neglected. When renal casts are present in considerable numbers—say, several in each low-power field of the microscope, or more—there is undoubtedly a destructive renal lesion present, particularly if accompanied by red blood cells. In recent lesions the casts are mostly of the epithelial type or are partly granular with adherent epithelial cells. In less recent lesions the casts are of the granular and hyaline types.

The Blood Urea.—A normal value of the blood urea does not exclude nephritis. It is only in the more severe degrees of acute nephritis or in the later stages of chronic nephritis that elevation of the blood-urea value occurs. In investigation of material of this type it is rare that other causes of increase of the blood urea are found. A raised blood-urea value is significant of nitrogen retention.

The Urea-concentration Factor.—The ratio of the blood-urea value to the urea content of the fasting sample of urine shows significant variation in the more advanced degrees of renal failure but may show little departure from normal in patients with undoubted destruction of renal parenchyma.

The Urea-concentration Test.—Concentration of urea in the urine after a test dose of urea and under controlled conditions is valuable in assessing the degree of renal insufficiency in renal disease, but may show normal figures in patients with subacute nephritis and with milder degrees of chronic nephritis.

Clinical manifestations of nephritis are more commonly present in acute and subacute nephritis than in the subchronic groups, in which evidence from clinical examination may be scanty or wholly negative.

Each case must be considered on the summation of all data available, but the occurrence of persistent albuminuria and of renal elements and blood in the urinary deposit provides the most valuable diagnostic criteria.

Summary

The classification of 110 cases of albuminuria in adult males is discussed.

Incidental albuminuria occurs in 0.55% of otherwise healthy adult males. Of these 28% can be classed as orthostatic albuminuria, 20% as albuminuria without evidence of nephritis, 13% as subacute nephritis, 28% as subchronic or chronic nephritis, and 11% as due to various infections of the urinary tract.

Subacute nephritis of mild degree is common as a sequel of respiratory infections. Some of these cases progress to chronic nephritis.

The aetiology of chronic nephritis remains obscure.

The occurrence of persistent albuminuria with an abnormal urinary deposit provides the simplest evidence of renal pathology.

I am indebted to Dr. David Rorie, chairman of the Aberdeen Medical Boards, and to Dr. T. D. Kennedy of the Department of Health for Scotland, for assistance in carrying out this work; also to Prof. David Campbell and Prof. R. S. Aitken for permission to publish notes of two cases admitted to their wards in the Aberdeen Royal Infirmary, and to the latter for much helpful criticism.

HYPERTHYROIDISM: RELATION OF THE BASAL METABOLISM TO THE CLINICAL SIGNS

BY

A. B. ANDERSON, Ph.D., M.R.C.S., L.R.C.P.

Clinical Biochemist, Glasgow Royal Infirmary; Lecturer in Pathological Biochemistry and Carnegie Teaching Fellow in the University of Glasgow

A great many data bearing on the basal metabolism in thyroid disease are available, and these have been collected and reviewed by Means and Burgess (1922), Boothby and Sandiford (1924), and Du Bois (1936). In their classifications the diagnoses of exophthalmic goitre, toxic adenoma, clinical thyrotoxicosis, etc., are compared with the basal metabolic rate. In this investigation an attempt has been made to correlate the presence or absence of the clinical signs on which a diagnosis of hyperthyroidism is usually made with the basal metabolism found. A preliminary report on the earlier cases in this series has been made elsewhere (Anderson, 1937).

Methods

The series consisted of 230 patients, of varied ages and both sexes, who had been transferred to the metabolic wards from the medical or surgical wards for determination of the metabolic rate. The presence or absence of the following clinical signs was noted:

1. **Enlargement of the Thyroid.**—Any palpable enlargement, whether generalized or local.
2. **Exophthalmos.**
3. **Tremor of the fingers of the outstretched hands.**
4. **Tachycardia.**—A pulse rate above 90 while at rest in bed.
5. **Sweating.**—Determined by palpation of the skin and from the history.
6. **Loss of Weight.**—Determined from the history given by the patient.

The basal metabolic rate was determined by the open method, using the Douglas bag and Haldane gas analysis. The rate was calculated with the aid of the Du Bois tables for average basal metabolism per square metre as modified by Boothby and Sandiford (Peters and van Slyke, 1932). In order to get satisfactory readings the patient practised breathing through the valves and into an old bag for several days until thoroughly used to the apparatus. Then the actual determinations, usually two or three on successive days, were made. Several days' rest in the ward and familiarity with the apparatus were found to be essential for a proper determination.

Results

For simplicity in tabulating the results three main divisions were made—namely, enlargement of the thyroid with exophthalmos, enlargement of the thyroid without exophthalmos, and tachycardia without enlargement of the thyroid. These were further subdivided according to the number of subsidiary signs present. The basal metabolic results were also divided into three groups: -15% to $+15\%$, $+16\%$ to $+24\%$, and $+25\%$ and over. The divisions corresponding approximately to the normal range mild or borderline hyperthyroidism, and moderate to severe hyperthyroidism respectively. The results are shown in the table overleaf, which is self-explanatory.

In 3 cases, not classified in the table, exophthalmos but no enlargement of the thyroid was noted. In only one of

Approximately 40,000 Jews died in Nazi Poland in 1940. According to data published by Jewish communities in Poland. This is a vast increase in Jewish mortality and has no parallel in the history of Polish Jewry. A large proportion of the two million Jews in Nazi Poland are stated to be in poor health. An investigation by a Nazi medical commission to ascertain Jews' medical fitness for hard labour established that 40% of the entire Jewish population were unfit for physical work.

these was the metabolism in the group +25% or over, and at a subsequent operation this patient was found to have an enlarged right lobe, which was in great part sub-sternal.

Clinical Signs		B. M. R.			Total Cases
		±15%	+16% to +24%	+25% and over	
Enlargement of thyroid with exophthalmos	1. Tremor, tachycardia, sweating, and loss of weight	2	5	47	54
	2. Two or three of above signs	3	2	17	22
Enlargement of thyroid without exophthalmos	3. Tremor, tachycardia, sweating, and loss of weight	1	2	28	31
	4. Two or three of above signs	12	7	23	42
	5. One sign only	13	2	—	15
	6. No signs; simple goitre	19	—	—	19
Tachycardia without enlargement of thyroid	7. Tremor, sweating, and loss of weight	8	1	3	12
	8. Two or less of above signs	29	1	2	32
Totals		87	20	120	227

Discussion

This series of observations clearly shows a close connexion between the clinical signs and the basal metabolic rate. Cases in the first three subsections of the table might be said to be frankly hyperthyroid on clinical grounds, and the determination of the B.M.R. showed a raised metabolism in 101 out of 107 cases. In Subsection 4 some cases were clinically on the borderline and 30 out of 42 had a raised basal metabolic rate, while all (19) simple goitres were normal. The group of 44 patients showing tachycardia without enlargement of the thyroid were nearly all within the normal limits. One of the five whose B.M.R. was found to be +25% or over was a diabetic.

These results are in agreement with those of Means and Burgess (1922), who, from a study of 1,000 patients, of whom 300 were clinically thyrotoxic and 290 were borderline cases in which hyperthyroidism was suspected, came to the conclusion that those with an outspoken clinical picture of hyperthyroidism invariably show increased metabolism, those with goitres but no signs or symptoms of abnormal thyroid function for the most part show normal metabolism, and those with atypical or incomplete clinical evidence of abnormal thyroid function may show normal or abnormal metabolism. Means (1937) from a further experience of a very large number of cases is still of this opinion. Unfortunately these authors do not state on what signs the diagnosis of abnormal thyroid function was made.

I have not used any of the formulae for determining the B.M.R. from pulse rate and pulse pressure. It is generally recognized that these methods give accurate results in about half of the cases only (Rabinowitch, 1935; Frank, 1935). Du Bois says: "If after making the history and physical examination the physician decides that the patient needs a basal metabolism test, it is advisable for him to record in writing his estimation of the basal metabolism rate. Experienced clinicians can usually do this with surprising accuracy, but even they find occasional large discrepancies."

The present contribution shows that from a classification of six clinical signs it is possible to draw conclusions as to the level of basal metabolism with a fair degree of accuracy, although there are occasional discrepancies. The possibility of making a reasonably accurate guess does not detract from the value of a determination of the basal metabolism in diagnosis, and this estimation is essential in borderline cases.

Summary

In a series of 230 patients of varied ages and both sexes who clinically were cases of hyperthyroidism or were suspected of hyperthyroidism, the basal metabolic rate was determined and was compared with the occurrence of the clinical signs—enlargement of the thyroid, exophthalmos, tremor, tachycardia, sweating, and loss of weight.

When enlargement of the thyroid was accompanied by exophthalmos and any other of the clinical signs the metabolic rate was high in 71 out of 76 cases; when enlargement of the thyroid was not accompanied by exophthalmos but all other signs were present the metabolic rate was high in 30 out of 31 cases, but when only two or three signs were present—i.e., in borderline cases—the metabolic rate was normal in 12 out of 42 patients; in simple goitre the metabolic rate was normal in all 19 patients; and 37 out of 44 patients with tachycardia without enlargement of the thyroid had a normal basal metabolic rate.

WAR DIFFICULTIES IN DIABETIC DIETS THE LINE-RATION SCHEME

BY

R. D. LAWRENCE, M.D., F.R.C.P.

(From the Diabetic Department, King's College Hospital)

Many diabetics who use the Line-Ration Scheme have recently found great difficulty in following it, owing mainly to the restriction of protein foods in the country. Often misapprehension of the details recommended in the scheme accounts for the patient's trouble; but in other cases even the Government's two extra meat rations in place of sugar do not supply all the prescribed protein, nor is there much supplementary unrationed protein. A few notes on this diet scheme will help to minimize difficulties and justifiably reassure patients. This has been done in detail in a War-time Supplement to my *Diabetic ABC* for patients, but doctors and their patients may be glad of the following facts and explanation.

Misapprehensions

When this scheme was first introduced in 1924 it contained a minimum of carbohydrate and a maximum of protein and fat, in the proportion of 1 C., 1.5 P., and 3 F. in accordance with the glucose:fat ratio of most diabetic diets then in use. Later the carbohydrate was increased and the fat cut down, so that the proportions for some years have been 1 C., 0.75 P., 1 F., and the scheme has been gradually modified in other ways. Originally it was stated dogmatically that equal numbers of black portions (C.) and red portions (P. and F.) must be taken to balance each other. This was soon modified in my own mind and practice, and for eight years my scheme, as published, has never insisted on this equal balance of blacks and reds, although many patients with old editions have religiously followed it—a procedure that is quite suitable for some types of patient. For some years now I have recommended that the balance of black and red portions need not be exact either in the day's total or at each meal (this I have always regretted a little, as it spoils the original naïve simplicity and dogmatism of the scheme). The explanation of the scheme states that 10 lines (10 blacks and 10 reds) should

be tried as a test diet: if it fails and insulin is necessary, then more carbohydrate—15 or more blacks (150+ grammes C.)—should be given in a definite arrangement to balance the insulin and the protein and fat (some 10 red portions) eaten at the various meals as desired and as most convenient. Now that protein supplies are scarce the insulin patient is fortunate in being able to increase his carbohydrate if he cannot obtain his pre-war amounts of protein and fat in quantities sufficient to safeguard weight and energy and prevent hunger. This may require a slight increase in insulin, but not in every case. If, therefore, he cannot get all his previous protein and fat, his health need not suffer if he uses more carbohydrate, and insulin when necessary. A prescription of 15 to 20 blacks and only 6 to 10 reds will usually keep him in vigorous health.

Unavoidable Difficulties

Diet cases without insulin are now often in an unavoidably difficult position, and I commonly prescribe a minimum, for an active life, of 10 lines—10 blacks (100 grammes C.+10 to 20 grammes unweighed green vegetables) and 10 reds (75 grammes P. and 90 grammes F.). Now the diabetic with two extra fat rations receives more than the fat content of 10 lines; but admittedly the animal protein obtainable often cannot reach 75 grammes of animal protein. The diabetic's rationed protein, including that provided by the two extra meat rations—equal to meat, bacon, and cheese to the value of 3s.—contains only 5 red portions a day. If he uses 1 pint of milk (3 reds) and can get an egg (1 red) or a helping of fish, poultry, or other unrationed protein food (2 to 3 reds) a day, 8 to 11 red portions of animal protein may be reached. If not, it should be remembered that this scheme allows very liberal supplies of animal protein, and if only some 6 red portions can be got occasionally (no doubt more on other days) the adult diabetic will not suffer from protein (nitrogen) shortage. His doctor should also remember that vegetable protein is not counted in the scheme, and from even limited supplies of cereals and legumes, and especially from green vegetables in the diabetic diet, this amounts to 10 to 20 grammes of protein a day. Diabetics, of course, depend for nutrition partly on the energy-calorific value of these proteins as well as their mere nitrogenous content; but any defect—in, say, 10 reds prescribed—in protein-calorific value is more than made up by the liberal two extra fat rations to which the diabetic is also entitled in place of sugar. But if the diabetic patient on diet alone cannot, with what carbohydrate he can tolerate without glycosuria, obtain enough protein and fat to maintain his weight and energy he is certainly in a difficulty. He has enough protein to satisfy his nitrogen metabolic requirement, but may not have enough to satisfy his energy even though his diet be supplemented by the extra fat, and is almost forced to use more carbohydrate than he can tolerate. Many are compelled to use insulin (usually one fairly small dose of protamine-insulin once a day is enough) to cope with the situation. Such diabetics may think this hard—the times are harder still—but they will soon get over their diet difficulties, and will find themselves, by the blessing of insulin properly used, in better health and possessing greater vigour.

Those diabetics who use my Simple (*Unweighed*) Diet Scheme are often in a similar difficult position. Their protein and fat foods have never been limited, except in obese cases, and I would now advise them to eat all of these foods that they can obtain. The amount will not, in present circumstances, be too much: their carbohydrate, although not weighed, is measured and restricted, and, if they cannot tolerate enough, insulin may be necessary, when never before

Carbohydrate foods, too, of the type that diabetics used liberally, are greatly missed. The grape-fruit, the orange, the baked or stewed apple, the tomato, which rounded off many gastronomic corners by supplying tasty bulk with little carbohydrate, are mostly gone. Diabetics on low carbohydrate diets must depend more on native vegetables and they are reminded that freshly grated cabbage, sprouts, celery, turnips, and carrots can make appetizing salads when lettuce and tomatoes are not available.

Conclusion

Let me conclude by emphasizing that if diet difficulties force a diabetic to need insulin, death or even ill-health is not threatened—as many think—but a new era of better health is sure to follow by its proper use and a suitable adjustment of diet. May I add, too, that diabetics, especially insulin cases, should carry on their person the information that they are diabetics, so that if they become ill or casualties in unknown surroundings their need for special treatment will be known. The Diabetic Association, 124 Baker Street, supplies suitable cards and diabetic identity disks on application.

AN ABDOMINAL CATASTROPHE WHICH DID NOT TAKE PLACE

BY

GEOFFREY E. PARKER, F.R.C.S.

I wish to report this case for two reasons: first, because it is an unusual one, even for a war injury; and, secondly, because I think it teaches a lesson. As many surgeons, like myself, are dealing with large numbers of bomb and shell splinter injuries for the first time, the conclusions to be drawn may prove of value.

Case Report

The patient, a member of a bomb disposal squad aged 24, was standing not more than six yards from a bomb when it exploded. On admission to hospital less than an hour later his condition was found to be excellent. In fact, of the eleven cases admitted from this "incident," his case appeared to be one of the least severe. He was bright and cheery, and not in great pain. The pulse was 84, regular, and of good volume. He had two penetrating injuries. One large piece of metal had passed across Scarpa's triangle on the left side, from its upper outer aspect and lodged just under the skin over the base of the triangle roughly over the femoral nerve. A second large fragment had entered the left flank just below and behind the postero-superior iliac spine, and there was no wound of exit. A radiograph (see illustration) showed this fragment to be lying somewhere in the left iliac fossa, having penetrated the wing of the ilium. The lateral radiograph was not satisfactory, but another was not taken owing to the rush of work.

There was deep tenderness in the left iliac fossa, but no rigidity or muscle-guarding, and peristalsis was clearly heard in this and all other quadrants of the abdomen. I concluded, therefore, that there was probably no intraperitoneal injury. The case was classified in order of urgency with the other wounded, and in due course was brought along to the theatre. The patient's general condition was still excellent. Morphine only had been given.

Operation.—The fragment in Scarpa's triangle was quickly removed, and the entrance and exit wounds and the track were excised. The wound was then packed with sulphanilamide gauze on account of some tissue necrosis from burning, and also because the danger of sepsis in a wound anywhere near the perineum justifies this precaution. After excising the upper wound of entry, the gluteus maximus and medius were found to be disorganized, and the area was full of blood. A small ragged hole was felt in the wing of the ilium, and this was enlarged sufficiently to admit two fingers. The iliacus muscle

was felt to be in a state similar to that of the glue, and after a little searching the bomb fragment, 2 by 3/4 by 1/2 inch, was removed. A careful search was then made for a hole in the peritoneum covering the iliacus, but none was found. I remarked to my assistant that it was a fortunate thing that we had found the fragment, otherwise I should have had to open the abdomen through the midline, in spite of the absence of signs

Radiograph showing position of bomb splinter.

of intraperitoneal injury. All bleeding was stopped and the wound packed with sulphanilamide gauze, which was passed through the hole in the ilium, and packed there as well as in the gluteal region.

Progress.—All went well for ten days. The bowels were open on the third day, and regularly after that. The temperature then rose suddenly to 100.2°, and remained at this level for three days. In addition there was deep pain in the left gluteal region, and some tenderness but no rigidity in the left iliac fossa. The pack had been taken out under evipan on the fourth day, and the wound had discharged some blood-stained serum only. On the fourteenth day the upper wound suddenly discharged some foul-smelling pus and gas, and the temperature fell to normal. For the next five days the wound discharged faeces and gas. The bowels were open daily, and no blood or pus was noted in the stools. That there was direct communication with the bowel was established by the fact that on giving capsules of indigo-carmin by the mouth the blue dye appeared on the dressing within a few hours. After the temperature had been normal for some days I ordered a gentle rectal washout and a barium enema, using a thin solution and under low pressure. The barium came through on to the dressing over the gluteal wound, but unfortunately the x-ray plates were not satisfactory. I think I had been overcautious for fear of disturbing adhesions, and had had the barium solution made too thin.

A few days later the faecal discharge stopped completely, and the wound is now granulating normally and is nearly dry.

Discussion

I do not pretend to understand the anatomy of this accident, but a number of possible explanations present themselves. (1) The fragment may have entered the peritoneum, injured the bowel, and then left the general peritoneal cavity again, to come to rest in the iliacus, protective adhesions subsequently forming. (2) The fragment may have injured the descending colon at the extreme lower limit of its partly retroperitoneal course, just before it becomes the sigmoid loop. (3) The fragment may have injured the blood supply to the colon over a small area, with the development of an area of necrosis. Adhesions would then form about the perforation in a manner similar to that which sometimes occurs in cases of perforating diverticu-

litis, a fistula being produced along the track of entry of the missile. (4) The large haematoma in the iliacus may have become infected by bacterial migration from the adjacent colon, the abscess thus formed discharging both along the track of entry of the missile and to a lesser extent into the colon.

Whatever the explanation may be, the lesson to be learnt would seem to be that if there is the slightest suspicion of an intraperitoneal injury, then, however trifling the physical signs, the abdomen must be opened and explored thoroughly. It would appear to be only a matter of luck that this man did not develop a spreading peritonitis.

My thanks are due to Prof. T. B. Johnstone, group officer in the sector in which I am a mobile surgeon, for permission to publish this case.

Medical Memoranda

Four Brothers with Neurofibromatosis

There are now numerous cases in the records demonstrating the hereditary nature of von Recklinghausen's disease. Thus Gardner and Turner (1940) traced the affliction through six generations, whilst Rocaz and Fiot (1938) found a Bordeaux family in which seven out of nine children had the malady.

In Lincoln four brothers have been under observation suffering from neurofibromatosis of the skin and subcutaneous tissue. One of these died at the age of 29, having developed paraplegia following spinal cord involvement. The three living are all of small stature, and their ages range from 50 to 60 years. In two of the patients the tumours have a generalized distribution, but in the third case the neck and forehead are alone affected. The lesions consist of a medley of tumours, some pedunculated and others sessile. There are areas of brown pigmentation, and some of the tumours have a bluish tinge.

Of four other children one is feeble-minded. Mental instability is not uncommon in von Recklinghausen's disease, and, while the brothers appear rational, two at least have a degree of acquisitiveness which does not always meet with the approval of the legal authorities.

The parents are dead and are said not to have had the disease. The father contracted a second marriage, which produced four normal children. From this it is deduced that the disease was transmitted by the first wife as a Mendelian dominant trait.

I wish to thank Mr. James Lyons for his notes on one of the cases, and Dr. M. L. Bery, M.O.H. for Lincoln, for permitting publication.

ANDERSON GARLAND, M.D., M.R.C.P., D.P.H.
Medical Officer, Burton Road Hospital, Lincoln.

The National Institute of Health of the U.S. Public Health Service is organizing a new unit for research into some of the many problems of the ageing. It is to be called the "Unit on Gerontology." A statement on the aims of this unit (*U.S. publ. Hlth. Rep.*, 1940, 55, 2099) points out that the problems of ageing are not limited to the diseases of the aged. They are divided into three major fields of investigation: (1) the biology of senescence as a process; (2) the human clinical problems of ageing and of diseases characteristically associated with advancing years; and (3) the socio-economic problems of a shifting age distribution in the population. The Unit on Gerontology is to concern itself with the first two of these. Information on the subjects under investigation and on methods of approach is asked for. Correspondence should be addressed to Dr. Edward J. Stieglitz, Investigations in Gerontology, National Institute of Health, U.S. Public Health Service, Bethesda, Maryland, U.S.A.

Reviews

GENERAL EPIDEMIOLOGY

Plague on Us. By Geddes Smith. (Pp. 365. 16s. net, or 53.00.) New York: The Commonwealth Fund; London: Oxford University Press. 1941.

To write a sound and readable book on epidemiology may not be so hard as to translate the Odes of Horace, but of the many who have tried few have succeeded. Dr. Geddes Smith has written a book which is both sound and eminently readable; it is intended for the general reader, but the British physician will learn much from it. In these days of intimate association with the United States, it has often been remarked how superficial is the knowledge of American history and institutions possessed even by educated Englishmen. How few of them even know the name of the great chief justice Marshall! It is the same with epidemiological history; very few, even of teachers, utilize the wide experience of a vast country which has produced many excellent observers. The author's studies of six epidemics—four of typhoid, one of amoebic dysentery, and one of haemolytic streptococcal infection—are admirably written accounts of logical and complete investigations, while the story of the epidemic of yellow fever in Philadelphia in 1793 is a thrilling one. Naturally much familiar ground is covered, too, but the description is so well done that it can be read with pleasure.

In an epilogue Dr. Geddes Smith permits himself to speculate. As Wilfred Trotter so wisely said, although the speculative, theoretical, and rational element in medicine has often impeded progress, when this element is excluded a science is in danger of sterilization. We should use pure reason, but with humility. The author thinks of disease as a "disturbance in a going system"—a phrase reminding one of Sutton's phrase (the Sutton of Gull and Sutton, a fine writer now almost forgotten), "disease is absence of rhythm"—and suggests that even in the frank infections the endogenous factors have more significance than we usually attribute to them. "Resistance may be general as well as specific. Immunological functions may be more closely tied into other physiological patterns than we have supposed; some of the fantastically numerous chemical tools postulated by the physiologist and the immunologist may do double duty. We may come to think of infection not as a special kind but merely as a special case of disturbance in a chemical system. We may find the way to reinforce the body at vulnerable points against threats from any quarter, infectious or otherwise, and without waiting for the threat to declare itself. At the very least we cannot hope to learn what we need to know about communicable disease without knowing more about the body that has it—and the body that throws it off. When pestilence falls on the people there is a story to tell. The story of the people who do not fall sick has never been told. Perhaps it is the most important part of epidemiology." Galen said 2,000 years ago, when writing of an epidemic, "The chief factor in the production of disease is the preparation of the body which will suffer it." That inevitably remained a vague generality, but with our increasing knowledge of physiology and biochemistry it may well be a pregnant truth. The study of those who do not yield to strain—whether the invasion of bacteria or more subtle foes—is as important as the observation of "patients."

This book is a real contribution to popular and even professional education. Its author freely acknowledges obligations to others, but his readers will owe him much gratitude.

BIOLOGICAL INTRODUCTION TO PSYCHOLOGY

A Biological Introduction to Psychology. An Introduction to Psychology for Students and Practitioners of Medicine. By R. J. S. McDowall, M.D., D.Sc. (Pp. 210. 6s. net.) London: John Murray. 1941.

Recent well-intentioned attempts to lighten the medical curriculum had as their most obvious result the addition of psychology to it. It will be readily admitted nevertheless that it is more important for the student to know something of the working of his patient's mind rather than the materia medica he will never have to handle directly. Then the difficulty arose that there was no suitable textbook for these students. Academic psychology has very little contact with their requirements, and not only is psychotherapy rent by faction but its literature is generally divorced from the biological and physiological viewpoint in which the student is being trained. True, up to the time of his death W. H. R. Rivers was building up a sane psychotherapy from a biological basis, but he was mainly writing for postgraduates. We therefore welcome Prof. McDowall's *Biological Introduction to Psychology*, which is couched in such language as the student who has done his biology and is learning his physiology can comprehend. The publisher rightly claims that the author accepts what is sane and reasonable in the various schools of thought, yet knits the seemingly divergent views together to form a coherent whole. It is at the same time so free from technicalities that the average man can gain much in the understanding of his fellow creatures and incidentally, we hope, of himself.

There is a certain amount of repetition in these pages, possibly deliberate, for every teacher knows that the student fails to take in everything at first hearing. Occasionally an apparent *non sequitur* obtrudes itself, the author having filled in the gap in his mind rather than on the page. There is a curious mistake on page 142. Sydenham did not found the College of Physicians, which antedates his birth by more than a century; indeed, he never even became a Fellow, probably owing to professional jealousies. Strictly speaking, Adler was not a pupil of Freud (p. xiii), and the author's exposition of his doctrine of organ inferiority (p. 103) is not quite accurate. Some of the case notes in Appendix II would have been more useful if an interpretation of the symptoms had been added. But apart from these minor criticisms we have nothing but praise for a book which covers the ground in an attractive way in such a small compass. It seems exactly adapted to the needs of the student who is expected to learn something of normal psychology at his pre-clinical stage. If the professed psychologist is inclined to declare the book to be superficial, we hope he may be stimulated to try to write a better one. From our experience of the medical student we have no hesitation in saying he will not find it an easy task.

THE PRACTICE OF SURGERY

The Science and Practice of Surgery. By W. H. C. Romanis, M.A., M.B., M.Ch., F.R.C.S., and Philip H. Mitchiner, C.B.E., M.D., M.S., F.R.C.S. Vols. I and II. Seventh edition. (Pp. 1,860; illustrated. 15s. each volume.) London: J. and A. Churchill. 1941.

A seventh edition of *The Science and Practice of Surgery*, which appears four years after the preceding one, has been prepared entirely since the war began and brings this well-known textbook up to date. Dedicated to the late Sir George Makins, it is in two volumes, in each of which a preface to the seventh edition appears along with that which introduced the first edition. In the face of a difficulty mentioned by the authors, that enemy action has rendered some of their notes and illustrations inaccessible, they are to be congratulated on the fact that the figures throughout the

work are plentiful and good, while the reproduction as a whole is excellent.

An appendix to the first volume deals with war surgery and is a valuable addition, but there will not be general agreement with certain statements in this section—for example, "Never drain head wounds, not even the scalp," and that all loose and depressed bone fragments must be removed. An account of intracranial aneurysms given in this section on war surgery, also, would be better placed elsewhere in the book, as it is brief and incomplete, and no mention is made of that type of aneurysm which may result from the injuries of war as well as those of peace—for example, the traumatic, fistulous variety. We are pleased to note that, despite the well-known view of one of the authors regarding the treatment of carcinoma of the breast, the radical amputation is advocated as the only treatment which presents a reasonable possibility of a permanent cure.

This edition has been advisedly shorn of some of the general discussion on bacteriology which appeared in the early chapters of previous editions, and of descriptions of certain amputations now only of historical interest. It shows revision chiefly in the sections on blood transfusion, the surgery of cleft palate and of the sympathetic nervous system. The word "sympatheticectomy" (pp. 362, 378, etc., and index) is cumbersome (why not sympathectomy?), and mention might have been made of superior cervical ganglionectomy for supra-oesophageal spasm (*Brit. J. Surg.*, 1935), a procedure which has now been tested by practice and appears to be one of the comparatively few operations on the sympathetic system established on a sound anatomical basis.

As previously, Vol. I is entitled "General Surgery," and Vol. II "Regional Surgery." As a student's textbook the popularity of this work, which has already been commented upon in previous reviews, is now well established, and the present revision should ensure its maintenance.

Notes on Books

MISS KINGDON WARD has described her views on *Stammering* in a volume of some three hundred pages (Hamish Hamilton Medical Books, 15s.). She says of stammering that "it stands entirely alone as a perfectly definite pathological entity." On the same page she says, "Stammering is seen to stand on a kind of fringe of nervous disorder: it is neither purely psychic nor the result of a lesion." The reader must be prepared therefore for some rather loose thinking and contradictory statements, especially as the author appears to use the terms "pathological" and "clinical" without any difference of meaning. There is no pathological basis of stammering; it is a clinical condition, and the classification given must therefore be a purely clinical one. The forms are classified as the typical stammer, the psychasthenic stammer, the hysterical stammer, the pseudo-stammer, the excitation stammer, the hurry stammer, the superficial stammer, and the war stammer. The pseudo-stammer, for example, develops at any age following an illness. Such a classification raises the question of when is a stammer not a stammer; and only too often the author loses herself in a wilderness of words. She does good service by drawing attention to the frequent need for psychological investigation and treatment in addition to speech therapy; but the length of the book and endless reiteration are discouraging to the reader in search of the author's views, which are essentially sound.

MISS MARY V. LACE'S book, *Massage and Medical Gymnastics*, was first published in 1936 with a foreword by Dr. James Mennell, who emphasized that the author's single aim was to set forth certain essentials that every student must know in a form that will be most readily assimilated, and serve as a foundation on which the masseuse and medical gymnast of to-morrow may build. A second edition has now been called for, and for this the whole text has been revised and some new matter added. The publishers are J. and A. Churchill, and the price is 12s. 6d.

Preparations and Appliances

AN IMPROVED EDITION OF THE THREE-WAY STOPCOCK

Dr. W. ALEXANDER LOW (London, W.1) writes:

A simple, though very efficient, improvement to such an old and tried arrangement as the three-way stopcock has now been devised.

The gas or gases from the anaesthetic apparatus are led direct to the stopcock through the inlet A. By rotating the knurled head B in an anti-clockwise direction the patient breathes in and out of the bag C, while the amount of rebreathing is con-

trolled by the spring-loaded expiratory valve D. If the knurled head B is turned in a clockwise direction, gradually more and more air is admitted at E, until the head has been turned fully over. In this position the patient receives full air and the bag is completely closed off, preserving the mixture in it for later use if required.

The mechanical advantages are that no rubber valves are used, the stopcock is gas-tight, and the spring-loaded expiratory valve permits controlled rebreathing with resulting economy. The sleeve can be withdrawn without the aid of tools for lubrication, and for this purpose it is suggested that a smear of vaseline be used. The stopcock has standard mounts and fits directly to the ordinary aseptic face-piece and gas-bag.

In practice I have found this an extremely useful piece of anaesthetic equipment. It is light and easily manipulated. It gives complete control where this is most needed—close to the patient's mouth. It can be used for almost any type of anaesthesia from a straight gas to gas-oxygen-ether. In particular, I have found it of great assistance in controlling patients under gas and oxygen during confinements, in which a rapid change of depth of anaesthesia is so often required.

The stopcock was made for me by the Medical and Industrial Equipment, Ltd., of 12, New Cavendish Street, London, W.1.

SATURDAY JULY 26 1941

VENOUS THROMBOSIS AND PULMONARY EMBOLISM

We have recently reviewed Nygaard's¹ monograph on blood coagulation, the best modern survey of the technical and physiological questions at issue. Nygaard and his colleagues^{2,3} have now supplemented this by a statistical study of 1,665 cases of post-operative venous thrombosis and pulmonary embolism which have occurred at the Mayo Clinic over a thirteen-year period. Although this seems a very high figure the average incidence was only 1% and the highest incidence of fatal embolism after any particular type of operation only 0.77%. There are, therefore, great difficulties in evaluating any form of preventive treatment. The aim of the analysis was to determine the comparative incidence of post-operative venous thrombosis and embolism in various types of surgical operation, the predisposing factors, and, if possible, the type of patient who was prone to this accident. It was hoped also to determine the general relation between clinically diagnosable thrombophlebitis and pulmonary embolism from the standpoint of incidence and time of occurrence. The usual situation of post-operative venous thrombosis is in the veins of the lower extremities and the pelvis, and in these veins alone can a clot of sufficient size be formed to produce serious obstruction of the pulmonary circulation.

Thrombosis and embolism were found to occur commonly after operations on the female pelvic organs, in which there may be injury to, or ligation of branches of, the iliac veins. They are common also in operations of long duration or great magnitude in which there is considerable injury to tissue. Carcinoma and infection are significant factors, but the nature of the anaesthetic seems of no moment. The risk of thrombosis and embolism is greater in women than in men, but actual pulmonary embolism, fatal or non-fatal, is slightly more common in men. These complications are rare under the age of 20 and show a tendency to increase in the upper age groups. Obesity, blood diseases, cardiac disease, and disease of the peripheral veins are contributory factors, but in about a third of the cases there is no predisposing cause. Thrombosis and embolism may occur as early as the second or as late as the one hundred and fifteenth post-operative day, but the highest incidence is between the seventh and fourteenth post-operative days.

Perhaps the most important conclusion from this analysis is that there are often two or more distinct episodes of thrombosis or embolism, separated by an interval which is usually less than four days and rarely more than ten. This is particularly important in regard to pulmonary embolism. Multiple distinct episodes occurred in 23% of these cases and a high proportion of them proved fatal.

In fact, the highest incidence of fatal post-operative pulmonary embolism occurring in any group of patients which the authors were able to define for statistical study was in that series in which a clinical diagnosis of non-fatal pulmonary embolism had been made. If all fatal embolisms which were preceded by a clinically diagnosed non-fatal embolism could be prevented, the total number of the fatal embolisms would be reduced by more than a third. Culp⁴ makes the following additional points in a review of cases at the Johns Hopkins Hospital. Continuous intravenous infusions appeared to be a factor in producing thrombosis in the lower extremities. Untimely activity was often responsible for dislodging an embolus, and death might have been prevented if the thrombosis had been recognized. At necropsy it was found that in cases of femoral thrombosis careful measurements of the legs at 10-cm. intervals, beginning at the lower margin of the external malleolus and extending as high on the thigh as possible, revealed a definite difference in the size of the two legs even when no asymmetry was apparent on inspection. Since routine leg measurements of surgical patients before operation and before getting out of bed have been inaugurated, a number of cases of latent thrombosis have been recognized.

Among methods used to try to lower the incidence of fatal pulmonary embolism have been efforts to increase the blood flow, as by the use of thyroid extract, the application of heat to the extremities, placing the patient in a reversed Trendelenburg position, the frequent movement of the patient from side to side, and moving the lower limbs up and down. Smith and Allen⁵ have shown that, whereas the arm-to-carotid circulation time changed very little after operation, the foot-to-carotid circulation time increased by the tenth day to a value approximately 50% greater than the pre-operative average. Administration of thyroid usually prevented this slowing of the circulation in the veins, which ordinarily occurs after operation. Priestley, Essex, and Barker⁶ point out that the most rational method of preventing post-operative thrombosis is to reduce the clotting power of the blood by heparinization. It would obviously be impossible to treat all cases in this way, and they therefore concentrated on the important group of patients who had manifested evidence of a non-fatal pulmonary embolus. The heparin was given by continuous intravenous drip, and a minimum of ten days' treatment was found desirable. Heparin was given to fifty-five patients, and only two subsequently died of embolism; these deaths occurred early in the series, before the authors had realized the importance of continuing heparin for an adequate length of time. Out of all this careful work from the Mayo Clinic there are thus two very practical conclusions. The first is that it is the recurrent cases of thrombosis and embolism which are the most dangerous; and the second is that the danger can be very greatly mitigated by heparinization of all patients who manifest symptoms of an initial thrombosis or embolism.

The observations of Smith and Allen on the comparative speed of blood flow in the great veins of the arms and legs provide at all events a partial explanation for the infrequency of axillary thrombosis as compared with

femoral thrombosis, while the short distance of the circuit through which the blood has to flow in the upper limb is equally important. From the Mayo Clinic, again, Stover and Herrell⁶ report an extensive thrombosis of the right subclavian and axillary veins associated with thrombophlebitis, lymphoedema, and polycythaemia vera. Although thrombosis is a common complication of polycythaemia the axilla is a very uncommon location for it. The patient made a dramatic recovery after the removal of more than five litres of blood by repeated phlebotomy over a period of eight days. Not until the end of this vigorous venesection did the concentration of the blood return to normal. The only other treatment consisted of heat and elevation of the affected extremity. Three years ago R. T. Payne⁷ emphasized the significance of lymphangitis in the clinical picture of femoral thrombosis, and pointed out that pure thrombosis was often latent and revealed only by embolism or at necropsy. Veal⁸ makes a similar distinction between thrombophlebitis and thrombosis of the axillary vein. True thrombophlebitis of the axillary and subclavian veins is a very rare condition, and occurs most often in cardiac patients in whom there is a slowing of the blood flow. It is accompanied by both the local and the constitutional signs of inflammation. Primary thrombosis is by far the most common type of thrombosis of the axillary vein. It occurs most commonly in healthy individuals and on the right side. It often follows trauma, either direct or indirect (violent exertion being included under the latter heading), but it may arise during sleep, presumably as a result of compression of the axillary vein. Secondary thrombosis from malignant disease of the chest and axilla is undoubtedly important, but at the present time there is probably need to emphasize the greater frequency of the so-called primary or effort thrombosis. The immediate prognosis in the primary cases is good, and with complete rest, elevation of the extremity on soft pillows, and local treatment, the oedema subsides within a few days or weeks. Nevertheless, residual symptoms characterized by weakness, early fatigue, pain, and swelling on exertion, persist in a high proportion of cases, and there does not seem to be much that can be done about them except to protract the period of rehabilitation and to warn the patient about the possibility of their occurrence.

In concluding this brief review of recent work on venous thrombosis we may remind readers that the third most important site of thrombosis is in the cerebral veins, and, as pointed out recently in our columns by Martin and Sheehan,⁹ thrombosis of the cerebral veins is predominantly an accident of the puerperium.

SEBORRHOEA AND THE B VITAMINS

Apart from the fact that urticaria can be caused by various articles of food in those who are sensitive to them, very little is known about the effect of diet on the skin. Of late years there has been a tendency to attach less importance to internal measures in the treatment of the common dermatoses, such as eczema in all its forms, and to stress those external factors that may irritate and

inflame the sensitive skin. That this attitude may undergo another change of direction is suggested by a recent article by György,¹ in which he analyses the skin lesions in deficiencies of the vitamin B₂ complex and relates these to the problem of seborrhoea in man. He first describes the skin lesions observed in egg-white injury in rats. Rats fed on a diet rich in raw egg-white soon develop a dermatitis confined to the groin, the genitalia, the neck, and round the mouth—almost completely analogous to intertrigo in infants. Later, brown adherent scales and progressive alopecia appear round the inflamed areas. Occasionally the complete skin of the rat may be involved, and the condition resembles the typical exfoliative dermatitis of adults or Leiner's disease of infants. The eyelids are stuck together and covered with yellow scales. There are generalized alopecia and pruritus, and in black and piebald rats the fur loses its pigment. This condition, resulting from egg-white injury, is cured by the administration of biotin or vitamin H—the best sources of which are liver, kidney, yeast, and, to a less extent, cow's milk. György points out that egg-white injury depends on (1) the toxic effect of egg-white in the diet, and (2) the lack in it of the protective factor biotin. Denaturation of egg-white by prolonged heating or by proteolytic digestion makes it innocuous. It seems, therefore, that egg-white injury is due to a toxic action; it has been shown that it is not due to an allergic reaction. In this connexion it may be recalled that Moro has emphasized the toxic character of Leiner's disease, or erythroderma desquamativum, a disease almost entirely restricted to the first three months of life, especially in breast-fed infants. György points out that, next to egg-white, lactalbumin is the most indigestible protein common in food, and that the biotin content of human milk is low.

As distinct from the lesions of experimental egg-white injury, those due to deficiency of pyridoxine, or vitamin B₆, are symmetrical and affect chiefly the peripheral part of the body—in rats the nose, mouth, paws, ears, and tails. This distribution led earlier workers to identify the condition as pellagra, but it was found later that nicotinic acid did not cure so-called rat pellagra, that there was no coincident gastro-intestinal disturbance (as in human pellagra), and that photosensitivity played no part in the production of the skin lesions. The condition of pyridoxine deficiency was therefore called rat acrodynia—a term chosen, as György says, "without prejudice to whether or not the underlying disease is identical with acrodynia in human beings." Rat acrodynia is characterized by red, inflamed lips and nose, red ears, and red, often swollen, paws. Later the skin of the paws desquamates, the skin of the ears thickens, brown crusting occurs over the back, abscesses covered by scabs of varying thickness appear round the mouth and cheeks. In advanced stages the whole body becomes scaly, but there is only slight or no loss of hair. The scales often have the appearance of an inspissated exudation. Administration of pyridoxine may or may not cure the cutaneous lesions, which may, moreover, reappear after temporary improvement. When cure is not brought about by pyridoxine, improvement will follow when the filtrate fact

¹ *Ibid.*, 1940, 15, 817.

⁴ *British Medical Journal*, 1941, 1, 349.

⁵ *Arch. Derm. Syph.*, Chicago, 1941, 43, 211

of the B₂ complex is also given. It has been shown, too, that relapse after treatment with pyridoxine can be cured by giving pantothenic acid¹ (see *British Medical Journal*, 1940, 2, 230 and 601). It would appear, therefore, that rat acrodynia is the result of deficiency in more than one factor, and György draws an analogy with the treatment of pellagra in which riboflavin as well as nicotinic acid has to be given to produce complete recovery in some cases. He also refers to the various lesions caused by deficiency of the different components of the filtrate factor, such as panmyelophthisis, haemorrhage into the adrenals, injury to the liver, and decolorization of the fur. The last named, again, responds to pantothenic acid, first detected in the filtrate from an aqueous liver extract. A further complication in this already tangled biochemical story is the curative action of unsaturated fatty acids in rat acrodynia, which it is difficult to produce experimentally, even with complete absence of pyridoxine from the diet, if this contains a high quantity of unsaturated fatty acids. György finally notes that in diseases due to riboflavin deficiency, small, dandruff-like scales appear on the skin, and the cornea becomes vascularized. This vascularization of the cornea with ulcer formation resembles the clinical picture of rosacea keratitis, and he stresses that rosacea is typically a seborrhoeic condition.

What stands out from this investigation is the gross resemblance between the lesions of seborrhoea in man and the scaly desquamation of the lesions experimentally produced in the rat from deficiency of pyridoxine, pantothenic acid, and riboflavin, and by egg-white injury. György is, however, careful to point out that this resemblance does not justify the assumption that there is any causative relation between human seborrhoea and deficiency in one or more of the vitamins in the B₂ complex. He does, however, point out that, although there are microscopical differences in the human and the animal lesions, they may be the result of difference in reaction between these two mammals.

Discussing the distribution of the various vitamins in foodstuffs, György states that the normal diet is poor in biotin content, almost the only effective sources being kidney, liver, and yeast; the last two of these are also the best source of riboflavin and pyridoxine. In the past dermatologists have blamed in turn excess of fat, excess of protein, and excess of carbohydrate in the diet as causes of seborrhoea, and György points out that experimental evidence supports the view that unilateral excess of any one of these three has a causative relation to seborrhoea. There is, for example, the interrelation already referred to between protein and biotin, and fats and pyridoxine. From time immemorial yeast has been recommended for various skin diseases, and in 1913 Czerny and Keller recommended liver for the treatment of exudative diathesis in infants. The fact that yeast and liver have on the whole been disappointing therapeutic agents is probably the result of insufficient dosage. According to his experimental data, György estimates that for riboflavin, pyridoxine, and biotin to be therapeutically effective, as much as a half to one pound of dried yeast, or of fresh liver, would have to be given daily—a course of treatment which very few people could bring themselves to undertake. Incidentally he observes that in Germany a liver preparation rich in biotin is widely

used in the treatment of various skin lesions and disorders of the fur in dogs. It would seem, then, that the relation of these various vitamins to seborrhoea in man will have to be worked out by the controlled therapeutic administration of prepared concentrates or synthetic substitutes.

Lastly, we may welcome one further reason for the supreme excellence of milk as an article of diet, for milk is, according to György, the only really common foodstuff which is rich in both pyridoxine and riboflavin, and also contains an appreciable amount of biotin.

EATING AND DIGGING

It sometimes appears almost as though the Ministry of Food spoke with two voices—voices not always easily to be reconciled. In the many excellent notices and advertisements by means of which the public is told not merely how to make the best of available foods but actually how to raise its general dietetic standard, there would appear to be a consciousness of the gap between scientific knowledge and nutritional practice and of the opportunities now presented for bridging that gap. At other times, on the contrary, we hear the persuasive voice of the Minister, and through him presumably the policy of the Government, informing us what he has given back and what he hopes to give back of the peacetime foods "in short supply." Seldom, if ever, is the public told in plain words from official mouths that many of the changes necessary in wartime are changes for the better, that they should not be regarded at all as emergency steps, to be reversed at the earliest suitable moment, but as an instalment, and a considerable one, of very drastic changes in the dietary habits of the nation as a whole. Above all, it is necessary, if the public is to be reconciled to the changes, to show conclusively that they represent a genuine raising of general nutritional standards. Official propaganda to such purpose would to-day have an easier task than ever before. Many men have for some time now been educating the reading public, or instructing the listening public by platform lectures and radio talks, in the fundamental facts established to-day by nutritional science. Mr. Wokes¹—whose previous published work has been concerned chiefly with the more academic side of biochemistry and pharmacy—is to be welcomed as a valuable recruit to this small army of propagandist effectives. His book is comprehensive, simple, and accurate; and to combine simplicity with accuracy in popular exposition of scientific findings is a task whose difficulty can be fully appreciated only by those that have attempted it. Some of what he has written has, unfortunately, no longer the same validity that it doubtless had when he was preparing his manuscript, as when, for example, he makes an increased consumption of milk and cheese one of the corner-stones of the improved dietary he advocates. Nevertheless, as an exposition of the principles on which any improved dietary must be based, whether in wartime or in peace, with much useful practical advice to the woman in the kitchen as to how she shall "feed the brute"—the man in the street and at the bench—his "Penguin Special" would be difficult to improve on. One of the few misunderstandings in the book is due to the author's apparent belief that margarine consists entirely of completely hydrogenated fish oils, and so is devoid of the "essential unsaturated fatty acids," and that this involves some risk to health. On the other hand, what he has to

¹ *Food: the Deciding Factor*. By Frank Wokes, Ph.D., B.Sc., F.I.C., Ph.C. A Penguin Special. Penguin Books. (6d.)

say about the relation between increased protein requirements and strenuous exercise (or manual labour) is accepted "classical" nutrition, though it does not seem yet to have reached all of those in the high places where national policy is determined.

The historian of the future may well single out as one of the significant social phenomena of these times the obviously insistent demand of a large and growing public for simple but trustworthy presentation of scientific knowledge, as evidenced in particular by the steady flow of "Penguin Specials" that are concerned with just that task. Whatever prestige is to be gained by the prominent presence on one's shelves of certain brilliant and epoch-making expositions, a "Penguin" is assuredly not bought for any less worthy motive, or with any less determined purpose, than that it should be read and its contents mastered. Many of those who read and run now dig so that they may eat, and for them Mr. Carter's guide¹ to the allotment holder—another "Penguin"—gives valuable information on our food plants, the pests that beset them, and the way to store and to cook them. There are chapters on general topics, such as allotments, clamps, frames, manure, weeds. That the private gardener can contribute enormously to the national output of essential foods—especially if he is guided in his selection by Mr. Wokes and in his methods by Mr. Carter—is incontrovertible. But something more is clearly vital if the improved health of the country as a whole requires a radical change in the proportion and quantity of protective foods to be consumed by 45 million people. Mr. Watts's persuasively written pamphlet² is an eloquent and convincing plea for a return to "high farming," based upon a proper appreciation not only of the scientific basis for rotation of crops and the complementary nature of pasture and arable, but also on the much less frequently discussed social value of agriculture as a way of living. It enables one to see clearly the broad outline of a national regeneration based on the soil, and may legitimately be regarded as expression of a policy that logically consummates Mr. Carter's practical concern with the quality of the plants men eat and Mr. Wokes's practical concern with the quality of the men that do the eating.

THIRST AT SEA

In the *British Medical Journal* of November 15, 1924 (p. 928), Mr. W. Bernard Secretan, F.R.C.S., then in practice as a surgeon at Reading, wrote to recall two letters which had appeared on February 16, 1918 (p. 220) advocating rectal injections of sea-water for the alleviation of thirst due to a lack of drinking-water. One of these correspondents was Mr. Morley Roberts, to whom the idea had occurred in 1910 that death at sea from thirst when there was no fresh water could at any rate be postponed, and possibly altogether avoided, in this manner, and he recommended that a Higginson syringe should form part of a normal lifeboat's equipment. The other correspondent was the late Mr. George Wherry, F.R.C.S., of Cambridge, who independently suggested the slow injection of sea-water into the lower bowel by some simple apparatus. Mr. Bernard Secretan in his letter posed the question in this way: "Is hypertonic saline of a saturation akin to salt water tolerated by the bowel, and will water be absorbed from it in the colon, as in the case of ordinary normal saline; or will it produce, as in the case of purgative salts held in hypertonic solution in the intestine, a flow of fluid from the tissues into

the bowel?" Asking for an authoritative statement on these points he wrote: "If water can indeed be absorbed from hypertonic salt enemata, then surely steps should be taken to spread this knowledge to those who go down to the sea in ships. . . . Responsibility for a clear declaration as to the efficacy or the reverse of such hypertonic salt solutions should rest with the medical profession." Nothing came of this challenge, and it remained for Dr. C. G. Learoyd to embody the central idea in one of his graphic short stories published from time to time in the *St. Thomas's Hospital Gazette*. Briefly the story went thus, if we remember rightly: Before his ship went down the young doctor on board put a few things together for emergency use, including a Higginson syringe; with this implement he succeeded in relieving the thirst of his shipwrecked companions in the lifeboat by rectal injections of cold sea-water. Fiction may or may not be based on fact: the author is not on oath. A pharmacologist whom we asked if the idea is feasible said that it seemed to him that the body would be bound to lose water on the transaction, with intensification of thirst, because the highest recorded concentration of sodium chloride in the urine after taking large amounts of concentrated salt solution by mouth is about 1.6%, whereas sea-water contains 2.7% NaCl. This theoretical objection may be valid, but the question is urgent in these times and should be settled beyond any doubt. Either the rectal injection of sea-water relieves thirst and is good, or it will not work in practice and is bad.

COMPENSATORY ATROPHY

The numerous hormones discovered during the last few years have been widely advertised to the medical profession and equally widely advocated for the cure or relief of a variety of endocrine and other disorders. It is still doubtful, however, whether many of these claims can be justified. Indeed, the Council on Pharmacy and Chemistry of the American Medical Association has been so impressed with the discrepancy between the proven value and the advertised claims that it has decided not to accept testosterone, the male hormone,¹ chorionic gonadotrophin, the pregnancy urine hormone,² and, more recently, progesterone,³ for inclusion among its *New and Non-Official Remedies*. These substances, it considers, are still in the experimental stage and have not yet found a definite place in orthodox medical treatment. The theoretical basis of endocrine treatment has usually been the belief that if a disorder is due to insufficient production of a hormone, then substitution therapy with that hormone will secure relief. Some notable successes have supported this view, but the interrelations between glands are so extremely complex and readily disturbed that unforeseen adverse effects may also occur during treatment. Such substitution therapy, though it may relieve symptoms, is unlikely to encourage cure; rather will it do the reverse. There is ample evidence, which still accumulates, that in animals continued injection of a hormone leads to atrophy of the glands which normally produce that hormone. The endocrine glands appear, indeed, only too willing to let their proper functions be taken over by the relatively crude syringe of the physician. Thus thyroid treatment tends to atrophy of the thyroid gland, androgen therapy to atrophy of the testes, and adrenal cortical hormone treatment to atrophy of the adrenal. The extent and duration of such adverse effects in man are not yet fully known, but they certainly occur. It has been shown, for instance, that

spermatogenesis in man is seriously inhibited by androgen therapy. Selye⁴ has been investigating the general phenomenon, and has called it "compensatory atrophy" to distinguish it from the "compensatory hypertrophy" which takes place in the remainder after removal of part of a gland. He has found that in rats the atrophic effects of testosterone may still be present months after treatment has ceased. He believes, however, that the phenomenon of "compensatory atrophy" may be put to therapeutic use in disorders associated with hormonal hypersecretion. But attempts to induce such atrophy in a hyperactive gland by injection of further quantities of its already overabundant hormone are unlikely to succeed, as the immediate result will be an aggravation of symptoms. Selye hopes to overcome this fundamental difficulty by using substances chemically similar to but physiologically different from the hormone. This has become a theoretical possibility now that the chemical composition of many of the steroid hormones is known, and many substances differing slightly from them in structure can be prepared. In preliminary work on these lines Selye has shown that atrophy of the adrenal gland can be produced in rats not only by desoxycorticosterone but also by the chemically allied substances testosterone and progesterone. So, too, atrophy of the testes could be induced by androgen therapy and also by oestrogens and progesterone. The working out of methods of treatment based on this principle is likely to prove complex. It is, for example, unjustifiable to assume that pathologically overactive glands will necessarily be susceptible to such "compensatory atrophy" in the same way as normal ones. Diseases referable to overaction of the endocrine glands are, with the exception of thyrotoxicosis, relatively uncommon. Attempts to control thyrotoxicosis by administration of oestrogens, which tend to inhibit the thyroid, have not given encouraging results, nor have similar attempts to influence an overactive pituitary. Nevertheless the outcome of Selye's suggestions will be awaited with interest.

PHYSIOLOGICAL ACTION OF WELCH TOXINS

Bacterial toxins susceptible of acute pharmacological experiment are uncommon, not only because of the difficulty of obtaining a pure toxin suitable for investigation, but also because of their general prolonged latent period of action. Exceptions to this, however, are the staphylococcus toxin⁵ and certain of the anaerobe toxins, notably those of *Vibrio septique* and *B. welchii*. The early work on the physiological action of bacterial toxins was summarized by Trevan⁶ in 1931, and although not extensive it revealed analogies and differences between certain snake-venom effects and the actions of *septique* and Welch toxin.⁷ Since that date the work on snake venoms has been greatly extended by the Melbourne studies, and more recently certain of the bacterial toxins—namely, the toxin of the Type D Welch organism—have been included within the scope of their investigations.^{8,9} The ammonium-sulphate-precipitated toxin contains, according to their results, two non-specific impurities: one a histamine-like substance removable by precipitation with alcohol in the cold, and the other a cardiac depressor substance. With regard to specific effects of the toxin, it may be mentioned that the unneutralized toxin contracts the isolated guinea-pig jejunum. The main clinical effect of the intravenous injection of fatal doses in lambs is to cause convulsions, due to

a direct action of the toxin on the central nervous system, probably on the basal ganglia. The ultimate cause of death is either respiratory failure or cardiac failure accompanied by pulmonary oedema. Owing to the presence of the cardiac-depressant impurity the circulatory effect of large doses of the toxin could not be analysed satisfactorily. In rabbits small doses of toxin produced ataxia and loss of muscle tone, again probably central in origin, while larger doses caused a specific circulatory embarrassment. The development of a tolerance to repeated doses was a feature which this toxin showed in common with other active bacterial toxins. The haemorrhages in the heart muscle in lambs and the haemorrhagic pulmonary oedema in lambs, rabbits, and cats after intravenous injection are indicative of the severe tissue damage resulting from the toxin. In their further analysis the Melbourne authors found that the liberation of histamine from the perfused cat lung was a specific effect of injection of the toxin, but that snake venom was more active in this direction. The toxin also liberated adenylyl compounds from the cat heart and the perfused rabbit liver and an inactivating enzyme similar to what occurs with cobra venom.¹⁰ It is probable that the local production of adenylyl compounds in the rabbit heart partly explains the bradycardia in that animal from the action of this toxin. It is unlikely that adenylyl compounds liberated from other organs and tissues reach the heart in effective concentrations, as they are so rapidly inactivated by the blood and tissue enzymes. This is the multiple type of response to tissue injury which has been found in varying degrees with a number of toxic agents as in anaphylaxis, certain snake venoms, and peptone. The physiological approach has yielded in the hands of the Melbourne workers results valuable not only to the bacteriologist but also to those interested in the general pathology of the reaction of tissues to injury. When the studies of the enzymic activities of the Welch toxins are completed they too should form an interesting corollary to the above results. The fact that products of metabolism of the Welch organism and also the snake salivary glands have similar effects raises once again the age-old question of the functions of such substances in relation to both the organism and its environment, but leaves it as far as ever from solution.

EDUCATIONAL NUMBER IN ABEYANCE

If this year were anything like normal the *British Medical Journal* dated September 6, 1941, would be the annual Educational Number, with full details about the teaching and licensing bodies of Great Britain and Ireland and the other medical institutions and public services, and information about openings for practice and research and post-graduate study. But the acute shortage of paper, the upheaval of professional life, and the dislocation of the work of medical schools make it impossible to prepare even an abridged Educational Number for the session 1941-2 which would give satisfactory guidance in these times of flux and short-term planning. Therefore the usual classified information will not appear in the text pages of the *Journal* of September 6. The advertising pages of that issue will, however, be open to announcements by universities, colleges, and other teaching and examining bodies, and by publishers and manufacturers, etc., who wish to bring their services and goods to the notice of intending students of medicine and newly qualified practitioners. Such announcements are of value to many besides regular readers, and those who look for them in a particular week of the early autumn must not be disappointed.

CHEST SURGERY IN WAR

This is the last of a short series of articles based on lectures given at the British Postgraduate Medical School, Hammersmith

DRAINAGE OF THE PLEURA

BY

R. C. BROCK, M.S., F.R.C.S.

Although pleural drainage does not afford a subject so dramatic as certain other features of war surgery of the chest, such as the removal of foreign bodies, it is perhaps more important than any other. It profoundly influences both mortality and morbidity, and is probably the greatest single factor in determining the length of invalidism, which in a mismanaged or unfortunate case may be lifelong. Like the treatment of pleural infection in civil work it can be conveniently considered under three headings: (1) when to drain the chest; (2) the provision of adequate drainage; (3) when to stop drainage.

When to Drain the Chest

Apart from the presence of frank suppuration the question arises as to drainage in less precise circumstances. It is well to remember two guiding principles which are of value in deciding whether or not to drain the peritoneum and which may well be applied to the pleura: (a) Is a condition present which the pleura cannot deal with by itself? (b) Is it anticipated that a condition will develop which the pleura will not be able to deal with by itself? We have a shrewd idea of what the peritoneum can deal with by itself, and I am coming to the conclusion that the pleura can deal almost as effectively with a certain amount of contamination, provided (a) the lung is healthy and no fistula is present; (b) no infected foreign body is present; (c) there is no infected chest-wall wound.

A penetrating chest wound (other than a small one without haemothorax or pneumothorax of any size) should be excised and either sutured, if only a few hours old, or packed open. The question arises as to whether the pleura should be drained in these cases. If the wound is large and with much laceration and contusion, or if there is a retained foreign body or damage to the lung, then the pleura should be drained by means of an air-tight intercostal catheter connected to an underwater seal and left in place for forty-eight or seventy-two hours. In fact, the surest general rule to follow is to drain every time. An intercostal catheter in use for two to three days can do no harm, and although perhaps unnecessary in some cases, will be responsible for averting disaster in many others. I have seen undrained cases of this type heal satisfactorily even when a haemothorax was present and had not been evacuated; the deeper layers have healed over and the haemothorax has been successfully treated by aspiration, thus proving that the pleura has been able to master some contamination at any rate. On the other hand, I have seen an even larger number of cases in which infection has supervened, drainage has been needed, and a long period of disability has resulted. There is no doubt that it is most unsafe not to drain if the pleura has not been sucked clear of blood and serous exudate before the chest-wall wound is closed; any such residuum is a dangerous culture medium to leave in the pleura.

Although routine drainage for two to three days is recommended, it is permissible for a surgeon familiar with the chest not to drain in selected cases, provided he is able to watch the patient closely himself for at least seven to ten days.

DANGERS OF SUTURING TOO SOON

When the first war casualties began to arrive from France we found that many of the chest wounds had been excised (often very incompletely), sewn up tight without drainage even when the lung had been incised to remove a large foreign body, and then transported within a few days. Much of our work consisted in taking out stitches, packing open the wound, which was the centre of a severe, spreading, sometimes gangrenous, cellulitis, and inserting an intercostal catheter into the infected pleura. Severe or fatal anaerobic infection may occur, and at the very least the patient has to face weeks and sometimes months of slow convalescence from a total pleural suppuration, with the lung perhaps completely collapsed and often containing one or more foreign bodies. The catastrophe could have been easily avoided in almost every case if the chest-wall wound had not been sewn up tight, but had been left open, and if a temporary intercostal drain had been used.

There is no doubt that these disasters have occurred owing to misunderstanding of the teaching about the treatment of an open sucking wound. It is generally taught, and generally accepted, that these wounds must be closed at all costs. That is quite correct; they must be closed, but not necessarily sutured. It is not safe to excise and sew up tight a big wound of the chest wall with lacerated and contused muscles; in the thigh or arm such a wound would not be sutured but would be packed open initially until the risk of spreading infection had passed. It is not possible to ignore a basic surgical principle such as this. The muscles and fascial planes overlying the thorax, far from being immune, are very susceptible to infection, which may rapidly give rise to a severe phlegmon. Unless, therefore, the wound is relatively simple, is completely excised soon after being received, and can be watched personally for at least a week, it must not be sewn up. A flat pad should be laid over it and secured by properly applied firm strapping. Such a wound is closed mechanically, but surgically it is still open. The pleura should be drained, as stated above, for two to three days. If it is then found that the lung is adherent and the deeper layers of the wound are shut off from the pleura the drainage tube may be removed, although careful watch will have to be kept for reaccumulation of effusion, which will need drainage again if aspiration reveals that it has become infected. The parietal wound can, and in fact should, be closed by delayed suture after a few days if the risk of spreading infection seems to have passed.

The management of a haemothorax may present many difficult problems, but one of the greatest dangers to be on the alert for is the onset of infection. This may not occur until as late as ten to twenty days after receipt of the wound, and may lead to death from anaerobic infection in a patient who had appeared to be almost convalescent. Presumably infection occurs from sloughing of devitalized lung tissue in the track of the missile. Close watch must be kept for the onset of infection; the temperature may be no true guide, but a rise in the pulse rate is significant. The fluid in the chest must be sampled at least every other day, and should be examined at once for evidence of infection. It is not enough to send a specimen to the laboratory. The haemothorax itself is an excellent culture medium, and much information can be obtained by its direct study; when infected the blood may

smell, haemolysis occurs, the colour changes to a purplish hue, and if a direct smear is examined micro-organisms will be seen. Culture in the laboratory will only confirm these findings. It is most important that samples of fluid aspirated from the chest should be kept by the patient's bed and properly labelled so that they may be available for inspection at any time. It is a common but nevertheless stupid habit to throw valuable evidence of this sort away and not to preserve it for future reference.

Once infection of the haemothorax has occurred drainage is needed. The type of drainage is considered in the next section.

Provision of Adequate Drainage

In a certain small number of cases pleural infection can be satisfactorily overcome by repeated aspiration of the exudate, but though this minor procedure is occasionally successful it is wrong to put it forward as a safe or standard method of treatment, except to tide over a few days, or two to three weeks at the longest. The same applies to intercostal drainage, which is invaluable as a temporary measure—in fact, is often life-saving—but will allow rapid and safe healing of pleural suppuration in only a few cases. It is a great mistake to imagine that all will go well and that rib resection can be avoided just because the patient looks and feels better and the temperature has subsided. The fundamental principle of civilian surgery still holds good, that in almost every case of empyema the adequate drainage provided by rib resection is essential to allow perfect healing in the shortest time and with the minimum of disability. To continue with a small intercostal drain for more than a few days is to expose the patient to the grave risk of a chronic empyema. The step of rib resection is a small one, should take only a few minutes, can be performed under local or a short gas anaesthesia, and should be no burden even to a very ill patient.

At the same time it is important not to drain the pleura too early. In war wounds, as in the synpneumonic pleural infections of civil life, there is usually diffuse infection of the whole pleura with no localization. If drainage is performed too early a total empyema results, the lung often remaining collapsed down on the hilum; in others the lower lobe expands more rapidly than the upper lobe, the drainage point is soon shut off, and a large residual or imperfectly drained anterior pocket is left, usually extending to the apex. These cases have been only too common and have proved to be very difficult to treat: they tend to become chronic, take months to heal, and leave the patient with an impaired respiratory function on the affected side. In many it has been almost unavoidable when aspiration has been difficult and unsatisfactory owing to the debris of infected clot, and the patient has been so desperately ill that early intercostal drainage has been needed as a life-saving measure. But unless this is the case, tube drainage should be postponed and aspiration persisted in until the pleural infection has become localized to give a true abscess. The aspiration must be performed regularly and efficiently and not infrequently and perfunctorily; by keeping the pleura as dry as possible not only is toxæmia diminished but the ultimate empyema will be a small one and therefore quicker to heal when it can be adequately drained by rib resection.

For the usual posterior basal empyema the best drainage is given by resecting about 3 cm. of the ninth rib just outside its angle. If a lower rib is taken not only is there risk of wounding the diaphragm but in the natural process of healing the ascent of the diaphragm will shut off the drainage hole and may cause a chronic empyema. Simi-

larly drainage too far forward is to be avoided; a tube inserted in the mid-axilla or anterior axilla cannot drain the posterior pleural recess efficiently, and a chronic empyema is almost certain to follow. Unless the patient has a pleuro-bronchial fistula there is no reason to fear turning him on his good side to resect a rib in the proper place at the back; to try to work with him lying on his back is inefficient and footling. If a broncho-pleural fistula is present the operation can be performed with the patient sitting up and under local anaesthesia; it is probable, however, that if the fistula is of any size a preliminary intercostal catheter will have been inserted earlier.

It is best to connect the drainage tube to a simple empyema bottle; this enables the pus to drain away cleanly, saving much labour, disturbance, and discomfort from constant changing of pus-soaked dressings, and it encourages expansion of the lung by maintenance of a mild negative pressure.

When to Stop Drainage

The termination of pleural drainage is a most important phase, and may be difficult to assess exactly. When drainage has been used as a safeguard in the presence of a certain amount of pleural contamination it can be stopped in two to three days: but when it has been needed because of an established infection the problem is quite different. There is no doubt at all that mismanagement of the drainage tube or its too early removal is responsible for much unnecessary suffering and a great deal of permanent crippling. Unfortunately the correct management of this phase has been understood during only the last decade or so, and the knowledge is still far too scantily appreciated. This is at once seen if standard surgical textbooks are consulted; it will be found that no correct rule is given as to when the drainage tube should be removed, but only some quite incorrect rule-of-thumb advice such as "after three weeks" or "when the discharge stops" or "when the discharge becomes thin." There is only one safe time to remove the tube, and that is when it is no longer possible to demonstrate a cavity in the pleura. This is a rule that cannot be too widely appreciated or stressed too much. Failure to observe it is responsible for more chronic empyemas than any other single cause.

In the healing of a simple acute abscess, provided drainage is maintained adequately, the walls collapse together and adhere by granulation until the cavity is completely obliterated: the discharge then ceases, the skin grows over, and healing is permanent. The proper healing of an acute empyema is no different: provided adequate drainage is maintained the walls come together (that is, the lung expands: collapse of the parietes is of course avoided by proper exercises) and adhere by granulation—that is, there is progressive symphysis of the visceral and parietal pleurae until the whole pleural space is closed. Then and then only should the drainage tube be removed. The final track from pleura to skin will close simply and certainly, and permanent cure follows. Should the tube be taken out when a pleural pocket still remains, progressive and satisfactory healing may follow, but it is much more likely that a chronic empyema will occur. Even if the skin heals over temporarily a latent pus pocket remains to be a constant source of toxæmia, and sooner or later (perhaps weeks or months, perhaps many years after) will flare up and lead to "recurrence."

The best way to decide the problem of tube removal is to investigate the size and extent of the cavity by a pleurogram—that is, radiography after instillation of a radio-opaque fluid or oil such as neohydriol or lipiodol. This should be done when it is felt that the cavity has

diminished to a reasonably small size; from a study of the size, shape, and disposition of the cavity any necessary adjustment in the size and disposition of the drainage tube can be made. Thus it is usually necessary to shorten the tube in the later stages of healing, but it may be shown that not shortening but lengthening is needed if a high-up or anteriorly placed loculus is not to be shut off and become chronic.

Measures Promoting Lung Expansion

It is impossible to speak of pleural drainage without referring to the measures to be used to promote lung expansion and, incidentally, to prevent flattening or deformity of the chest or scoliosis. In stubborn or difficult cases lung expansion may be aided by constant negative suction (e.g., 2 to 8 cm. Hg negative pressure) applied by means of a Roberts bottle or, when the patient is mobile, by Brock's portable suction apparatus. This suction can never make up for inadequate drainage; it must never be used to suck pus out through a small hole when it should really run out through a large hole, nor should it be allowed to replace proper breathing exercises, to which it is merely complementary. These should be taught by a trained masseuse, and the patient should be impressed with the need for daily hard work in their observance; it is not enough for him to spend a gentle ten to twenty minutes with his instructor each morning, but he should try to devote to them a total of several hours a day by himself. The best type of exercises are those of the inspiratory type described by McMahon, which aim at restoration of proper and symmetrical costal breathing and controlled diaphragmatic movements. They are supplemented by appropriate remedial exercises to maintain proper posture. The use of the homely "blow-bottle" is not to be recommended, although it has a place in certain selected cases.

The treatment of an empyema should, moreover, be ambulatory as soon as the patient's general condition allows him to get up. Proper expansion of the lung and obliteration of the infected pleural dead space is thereby hastened, always provided adequate and correctly placed drainage is maintained.

As a contrast, how often do we see those unfortunates who have been ill for months, perhaps years, still in bed most of the time, with a horribly flattened, deformed, and seriously impaired chest and a continuously running small sinus that either has a minute tube or no tube at all, or, worse still, has a strip of ribbon gauze tucked in it. Let us try to save our wounded fighting men and civilians from this fate—so tragic because it is avoidable, but one which has befallen many in the past.

Under proper and thoughtful guidance the healing of an infected pleural space can be achieved in a short time and with no permanent disability at all; inattention to the simple principles of drainage laid down here may result in the production of a chronic empyema which will entail perhaps a lifetime of suffering and disablement to the patient, and great economic loss not only to himself and his family but also to the nation, which may be called upon to grant him a permanent pension. In addition the services of a useful citizen or soldier may be unnecessarily lost. Not the least of the tragedy is that in most cases it could have been completely and easily avoided by taking proper care at one phase of management of the healing stage; in most this phase is that of regulation of the drainage tube, and occurs through failure to appreciate the seriousness of its casual premature removal.

Remember that the treatment of pleural suppuration does not consist in doing an operation on the patient. The operation for providing adequate drainage is only an

incident in treatment, albeit an important one. Treatment is concerned with securing and maintaining full lung expansion and thereby complete healing of the infected pleura. So often the surgeon's interest (and indeed the interest of all the patient's attendants) becomes progressively less as the days pass into weeks after operation. The reverse should be the case: interest and attention should increase as the stage of healing advances, and in the final stages of obliteration the most scrupulous care is needed to manipulate the tube and arrange its removal at the correct time. Only when this is fully appreciated will the number of crippling and chronic empyemas caused by this war be diminished.

CLEARANCE OF URBAN AIR-RAID CASUALTIES AT THE PERIMETER

BY

A. MASSEY, C.B.E., M.D., D.P.H.

Medical Officer of Health, City of Coventry

G. G. ALDERSON, B.A., M.B., F.R.C.S.

Group Officer, Coventry Area

AND

C. F. BROCKINGTON, M.A., M.D., D.P.H.

Deputy Medical Officer of Health, County of Warwick

One of the major lessons taught by experience of severe enemy air attack is the danger resulting from a central location of general hospitals in vulnerable towns. Fortunately indeed are the towns possessing general hospitals at the periphery. But in the majority of cases the hospitals are on central sites, and thus it is that heavy damage to their personnel and fabric is now an unhappy commonplace. These things have obvious bearings upon casualty clearing schemes in the localities. The hospitals in a town are ordinarily the natural centres for the initial admission and classification of the more severe air-raid casualties pending outward transfer to affiliated base hospitals. The sequence of events then is: (1) collection of street casualties—inward flow of laden ambulances to central hospitals; (2) "sorting" and initial treatment of casualties at central hospitals—outward flow of other laden ambulances to base hospitals. The minor cases are, of course, treated at the first-aid posts.

When the Inner Ring is Heavily Bombed

This works well enough in raids with circumscribed incidents. But when the entire inner ring of a town is subjected to heavy and continuous bombardment there are obvious and serious difficulties owing to: (a) actual or potential damage to the central hospitals themselves; and (b) the danger entailed in bringing loaded ambulances through the zone of maximum bombing. These conditions are more liable to arise in the county borough of ordinary size, for in the larger cities the inner ring is of such extent that it cannot be completely "plastered" in quite the same way.

In the average county borough of known or supposed vulnerability, therefore, whose hospitals are located centrally, it is well to have in readiness a scheme for the clearance of casualties at the perimeter. This means that, on a given signal to the ambulance depots, all ambulances will be instructed to turn outwards following the collection of street casualties and deliver them to the nearest prescribed clearing station at the perimeter. These stations may be provided by upgrading selected first-aid posts. In upgrading posts it is probable that staffing and equipment are of more importance than elaborate structural works, for "sorting," resuscitation, and recording are the primary functions of the clearing station. Patients usually travel better before operation than after, and the mass of

operative work will be done in the outside base hospitals following transfer from the clearing stations.

Experience in Coventry last year indicated the need on occasion for such clearing stations; in fact, some such arrangements had to be improvised at the time to meet the demands of the big raids in November, 1940. Following that, a more concrete scheme of casualty clearance at the perimeter was devised, and this proved its value during the heavy raids on the city in April, 1941. This will be appreciated the more when it is mentioned that the city's large central voluntary hospital was completely put out of action owing to severe damage sustained in April, and that the municipal general hospital, although still largely intact, occupies such a vulnerable site that considerable restrictions have of necessity been imposed on its use. It should be mentioned that the voluntary hospital authorities have already established a substantial nucleus of new in-patient accommodation in a building just outside the city boundary, and this will shortly be included among the clearing stations.

Outline of a Local Scheme

For purposes of publication, a description of the local scheme can only be brief and in general terms. There are five stations (which are also first-aid posts) situated respectively in the northern, eastern, southern, south-western, and western sectors of the town. All are school buildings, and each is approached readily from the city centre by a main road.

Two schemes of casualty clearance are recognized. Scheme 1 is operated in small raids, when the remaining central casualty clearing hospital—the municipal general hospital—is available for initial admissions. Scheme 2 is brought into use in more extensive attacks, and clearance is then to the perimeter. The decision as between Schemes 1 and 2 or regarding a switch from 1 to 2 on any particular occasion rests in the ordinary way with the responsible officer of the casualty services in city central control. The operation of Scheme 2 is initiated by calls to the city clearing stations, posts, and depots, and to the County of Warwick control. Thereupon it is understood that (a) the city ambulances will convey casualties from incidents to the clearing stations at the perimeter, and (b) county control will send county ambulances to the stations for the purpose of transporting casualties, after classification and preliminary treatment, to base hospitals in the reception areas. The clearing stations are linked up with the outside hospitals on a geographical basis in order that, so far as possible, cases from, say, a clearing station in the south proceed to a hospital that is also in the south, and so on. Fortunately there is a first ring of base hospitals which conveniently permits of this, and all these hospitals are within a dozen miles of the city. It is, of course, appreciated that the flow of casualties may have to be modified at any time according to circumstances. The more distant hospitals in the group are brought into use as necessary either for direct admission or for the reception of outward transfers.

In conditions of severe raiding telephone communications not unusually give out and messenger services may well suffer difficulties and delay. In these circumstances it is understood that the city clearing stations, posts, and depots will temporarily assume the initiative in the matter of clearing incidents in their respective zones according to Scheme 2. Similarly, county control will take appropriate independent action when communications with city control are inoperative.

Summary

In vulnerable towns the inner circle and the hospitals in it are always in special danger from enemy air attack. It is thus necessary in conditions of heavy central raiding in such towns to reverse the flow of ambulance traffic and direct it outwards to clearing stations at the perimeter. Schemes which can be brought into immediate operation should be available to this end in selected towns. This note describes such a scheme which, despite some residual faults that are still receiving attention, has worked with some success under rigorous test.

CASUALTY SURGERY IN AIR RAIDS

A second symposium was arranged by the Bristol Division of the British Medical Association on July 10, when, at a largely attended meeting under the chairmanship of Dr J. A. NIXON, casualty surgery in air raids was discussed.

Work of the Resuscitation Officer

Col. L. H. WHITBY said that 10% of all air-raid casualties required transfusion, the average amount being two to three pints, so that if a hundred casualties were received at hospital a stock of between twenty and thirty pints of transfusion fluid should be available for use by the resuscitation officer. "Shock" was a useful term for the lowering of vitality which resulted from injury, and its most striking manifestation was circulatory embarrassment or collapse represented by reduction in blood pressure. Serial blood-pressure readings were the most reliable index to the cases needing transfusion; the pulse was not nearly so reliable as had been supposed. An experienced reception officer could tell at a glance which cases should go to the resuscitation ward. Air-raid casualties fell into two broad groups: the neurogenic or psychogenic, and those showing very definite reduction in blood volume. The former were likely to respond to conservative measures—rest, warmth, morphine, fluids, and, most important of all, reassurance—but those with circulatory embarrassment owing to reduction in blood volume must be treated in addition by quantitative replacement approximately of the amount of fluid lost, and this must be made with a protein fluid.

In arranging facilities for serial blood-pressure observations it was not necessary to have a battery of sphygmomanometers: there should be a large supply of cuffs, and the instrument could be plugged in to points near the patients. It was essential also to know the nature and extent of the injuries if there was not to be failure to transfuse in a case which needed transfusion. Nothing should prevent the resuscitation officer slitting a victim's clothes from head to foot—a useful implement was a pair of carpet-maker's scissors—and making a thorough examination. Again, there were people who might suffer a great reduction in blood volume without an equivalent fall in blood pressure. Gross injuries would lead one to expect that the blood pressure would be almost unrecordable, but common sense would suggest that transfusion in such a case should not be withheld because the reading was not as low as might have been anticipated. Oxygen was of great value in cases exhibiting gross cyanosis, and there was much to be said for the only surgery which should be performed in a resuscitation ward—namely, the treatment of a penetrating wound of the chest to relieve the cyanosis and put the patient in a better condition to withstand operation. Once a patient had been resuscitated adequately he should be operated on without delay, otherwise the improvement in blood pressure and general condition tended to disappear.

Resuscitation did not end in the resuscitation ward. In cases with gross injury more transfusion might be required in the theatre. Movement from trolley to table and loss of blood at operation might undo some of the work previously done. In all such cases it was well for the last act in the resuscitation ward to be the setting up of a bottle of blood or plasma to accompany the patient to the theatre. The amount of blood lost was sometimes as much as 3½ litres. But one of the experiences of the present war was that patients might lose even such an amount and still survive for a few hours, and the essential difference between the casualties seen in the last war and the present one was that in the latter the time between infliction of the injury and treatment was very much shorter. Blood pressure was the only reliable indication that replacement of volume by transfusion had been sufficient. If a rise of from 10 to 20 mm. Hg per pint of fluid was not obtained, loss from an internal source should be suspected. As for the rate at which the fluid was administered, most people were in reasonable health before wounding, and a slow rate was not so necessary as when transfusing an anaemic person in civil practice. The rate sometimes induced a rigor—not all rigors were due to incompatible transfusions—but if the rate was slowed the rigor would disappear.

Some thought a blood transfusion service unnecessary because in the last war severe cases improved with saline; but if a casualty survived his haemorrhage his mechanical equipment for the restoration of his blood pressure would have come into action, he would dehydrate himself, and would be in a poor way on that account only, so that a pint or two of saline was life-saving. In the case of young people the first reaction to loss of blood was an intense vasoconstriction in an attempt to conserve blood which might keep the pressure at a reasonable level despite the fact that much blood had been lost. Clinically they appeared intensely pale on account of this vasoconstriction. Such patients were likely to collapse. If it was obvious that a person had suffered reduction in blood volume, transfusion should not be delayed.

Organization and Personnel

Prof. J. A. RYLE spoke of the organization and duties of personnel in a city hospital capable of taking more than one hundred casualties. The staff would include a surgeon in charge, a physician, a receiving officer, an anaesthetist, residents, and a radiologist, the appropriate number of sisters and nurses, also stretcher-bearers, clerical assistants, and so on. Perhaps, of the cases received in one night, about one-half would go to operation and about one-quarter through the resuscitation ward. The receiving officer must have considerable experience and be able to decide almost at a glance whether the patient had to be resuscitated or was ready for operation at once. Casualties did not arrive in a continuous stream; they were brought in four at a time by the ambulances, with short intervals between. A superficial examination was made, but the patient was not turned over or moved, and the decision was either "resuscitation" or "general casualty ward." A resuscitation ward was essential; such patients could not be dealt with adequately if scattered in several wards, and the ward should be in as safe and quiet a place as possible. The personnel should include a physician with two residents, one, at least, expert at transfusion, a sister, and nurses. The beds should be warmed and cradles put in position as soon as the raid started. The senior surgeon should not himself operate; his job was to decide when the resuscitated patients could be moved for operation. The decision as to the optimum time for operation was best made by the physician and the surgeon who went round and assessed the degree of recovery. He had the same function in the general casualty ward, but, of course, the resuscitation ward came first. It was useful to have a large supply of triangular bandages which could be put on any part of the body without much manipulation. All x-ray work should be done with a portable apparatus; it saved movement of the patients. After operation it was a good rule to return patients to the resuscitation ward for observation if there was reason for anxiety. It was only by close watching almost from minute to minute that decisions could be made. There was no need in the resuscitation ward to separate the sexes, and this enabled the resuscitation team to be concentrated in one place with their apparatus.

Dr. P. PHILLIPS (Bristol) said that at his hospital a dispenser was responsible for taking records of patients admitted. Differently coloured cards were attached to the casualties, all details were put upon them, and they followed the patients wherever they went. It had been found advisable to have two sisters in charge of morphine and of anti-tetanus injections. One apparently minor point, and yet not unimportant, concerned the removal of clothing. In view of the coupon system mutilation of the cloth should be avoided if possible, and a pair of tailor's scissors was useful for opening up the seams. He concluded with a tribute to the amazing fortitude and patience of the victims.

Operative Procedure

Mr. G. M. FITZGIBBON first endorsed what Col. Whitby had said about blood transfusion. Thanks to Col. Whitby and his assistants, the lives of many casualties had undoubtedly been saved. As an instance of the "miracles" that could be wrought, he mentioned the case of a man aged 60 who had a leg shattered and an injury to his arm; the blood pressure was unrecordable, and he seemed clearly about to die. He was given four pints of

plasma and his pressure rose to 100 mm. Hg. An amputation was then done above the knee and the arm injury attended to; within two days he was sitting up reading the paper, and he made an excellent recovery.

From the point of view of operative procedure, a large proportion of these cases differed in no way from those encountered in ordinary civil traumatic surgery, such as road and industrial accidents. The difference in some cases was the penetrating wounds caused by flying splinters and secondary missiles. The case he found difficult was the multiple "peppered" wound. It was astonishing what might underlie a small puncture wound of the abdominal wall. A great deal of time was wasted in exploring small wounds, but occasionally something was found that made it worth while. Another difficulty was abrasions with the almost incredible filth that was ground into them. If left to heal there were scars. He used a nail brush under a general anaesthetic to remove the greater part of the dirt. Again, there was the penetrating wound which went three-quarters of the way through a limb; if a débridement was to be done it was worth while making a counter-incision on the other side and trying to form a conical wound which could be thoroughly cleansed.

Mr. Fitzgibbon had been impressed by the effects of spraying raw surfaces with sulphanilamide powder; it did not interfere with granulation. He had had two cases of gas gangrene. One was a penetrating wound of the calf. The general condition was poor, and it was not thought that the patient could stand an amputation; therefore several incisions were made and the wounds packed with sulphapyridine; serum also was given. On the ninth day a haemorrhage occurred and the leg had to be sacrificed, but the patient's condition was better, and he eventually recovered. The second case was that of a woman with a minor wound of the tibial region. An extensive incision was made and packed with sulphapyridine; she was given serum, and made a perfect recovery without losing the leg. He also described operations on two chest wounds, and asked whether haemothoraces should be emptied. On the subject of burns, Mr. Fitzgibbon suggested that too many were tanned, making it very difficult to realize the extent to which necrosis would result. A second-degree burn might look suitable for tanning, but it might be found subsequently that the tan had raised the granulation tissues and not healed the epithelium. He thought that only cases in which the burn was obviously superficial should be sprayed.

Mr. E. ROCK CARLING said that the fundamental principles of surgery were quite unaffected by externals like war, though the organization of work in hospitals must be different. It happened not infrequently that a number of patients reached together the optimum time for operation, and it was important that there should be available during heavy raiding enough surgeons to supply the available tables. This was comparatively easy in a one-night "blitz," but difficult in continuous raiding. Surgeons must give up the idea of having beds of their own or of being able to select their wards. It was also important that during a heavy raid some surgeon or physician, or both, should be in supreme control. In the case of patients whose blood pressure would fall in due course he thought it was the opinion of the majority of surgeons that they should be operated on before the moment arrived when the pressure fell, and that transfusion must take place in the theatre and afterwards. If surgeons did not see their cases before operation, most careful notes should accompany the patient to the theatre.

With regard to "peppered" wounds, experience in the Navy suggested that the vast majority of these took care of themselves, although there was nothing more dangerous than an innocent-looking penetrating wound. A first-aid doctor remarked that on a particular raid night he had treated a certain number of small, innocent wounds of the scalp. "Yes," replied the surgeon who had received the cases, "you sent eleven in one night; four of them had foreign bodies in the brain, and the other seven were depressed fractures." As to débridement, they should have said long ago, "Lay your wounds widely open until you get to every possible recess." Scrubbing had been mentioned in connexion with abrasions. This was sometimes accompanied by severe shock and fall in blood pressure. Some surgeons had used liquid paraffin as a cleansing agent. On the subject of burns, convincing evidence had been put forward by

plastic surgeons that in third-degree burns where the skin was wholly destroyed coagulation should not be undertaken. Healing sometimes took place under coagulation, but it was healing with the loss of the amount of skin destroyed. Because of non-epithelization, and because tanning was a bad preparation for subsequent grafting, the plastic surgeon desired every third-degree burn to be treated by any means other than coagulation. If there could be certainty that a burn was third-degree the problem would be simple, but every burn which was third-degree was also in part first and second.

Mr. K. H. PRIDIE, speaking of first-aid work, said that insufficient use was made of a firm bandage over wool. He had only once seen a tourniquet which had definitely saved a life, but he had many times seen a tourniquet which caused extensive venous constriction. The dressings issued were too small for large wounds ; for Army casualties a bigger dressing was issued, with a large bandage which could be firmly tied. Those in attendance at the incident should put crushed limbs anatomically straight, and a firm bandage over wool would stop any haemorrhage. He added that doctors should go to the scene of an incident and supervise the work there. They should put a label on the patient stating, for example, that it was a compound fracture, so that on reception there would be no need to take off the firm bandage and cause fresh bleeding. There would be much better first aid if it could be arranged for patients to be treated by a doctor at the incident.

COMMUNAL FEEDING IN SCHOOLS THE MIDDAY MEAL AS AN EDUCATIONAL SUBJECT

[FROM A CORRESPONDENT]

In the years before the present war progressive establishment of central schools meant that a considerable number of children had to depend on the school for their midday meal. In many areas teachers took advantage of this provision by making the school meal part of the curriculum, building round it lessons in hygiene, food values, and even history and geography, as well as the more obvious instruction in cleanliness and good manners. This advance was limited in scope until wartime economy gave a new impetus to schemes of communal feeding. With the help of voluntary bodies and continual encouragement from the Board of Education the system of school canteens has made rapid progress and, in the reception areas especially, communal feeding in schools has become a feature of everyday life.

The requirements of a school meal are simple enough: it must be good, cheap, well cooked, and well served. By "good" one means that it must consist of wholesome food in the right proportions to promote healthy growth, with the addition of sufficient vitamins and mineral salts to meet the sum of the child's daily needs.

Provision should be Obligatory

Recent investigations conducted by experts and subjected to careful scientific analysis point strongly to the conclusion that the communal midday meal in schools should now be made universal. It is true that education, propaganda, and voluntary effort have already done a great deal towards the provision of school meals ; it may be true, as is sometimes argued, that in certain areas there is no local demand for communal feeding ; but these arguments carry little weight in wartime, when food problems are too complicated for the ordinary housewife, and when our future as a nation depends so much on the sound nutrition of our children. It is permissible to hold that there should be an obligation upon the local education authority to make this provision, and children should be excused from attendance only if their parents can show that they can and do provide an efficient substitute at home.

This recommendation is supported by a number of considerations, of which the following are perhaps the most important:

(1) The communal midday meal can be made an integral part of the daily education of every child. This should have been done in peacetime ; in war the argument is strongly reinforced.

(2) Good nutrition is so great an asset to the nation at any time that no chance should be missed of laying firm foundations in childhood.

(3) In wartime the need for sound nutrition is compelling, but the means of maintaining a high standard requires expert guidance. The best of our modern knowledge of food values can be applied through the communal meal, and in no other way.

These three points may now be considered in more detail.

1. Educational Value of the Communal Meal

Rightly considered, the school meal is an indispensable part of the curriculum at all ages. It is one of the best means of making a child fit to become a useful citizen. Habits acquired at meal-times remain with a child through life. Knowledge of food values ; simple daily experience in cooking and serving ; and patient instruction in the protection of food and the avoidance of waste : these will become part of the ordinary background of the adult if he has been well taught in childhood. Under present conditions school medical officers and those who undertake child welfare work have constantly to give advice to parents about feeding their children ; in general practice one of the most important therapeutic measures is advice on diet. The work of the whole medical profession to-day is hampered by the appalling ignorance of working-class parents about the most elementary principles of feeding. The guidance offered is often valueless, not from lack of good will, but on account of the fact that young fathers and mothers have never been taught when they were children.

The "food lesson" is a most important educational subject for both boys and girls, and it is never too soon to begin. The remarkable success of nursery schools in teaching good habits at table is an example and an encouragement, but the work must be treated seriously and be carefully organized, or much of its value will be thrown away. At present, where midday meals are served in schools, the whole affair is often a glorious rush with the one object of getting into the playground as quickly as possible. There is little attempt to inculcate good manners at table, and the service generally (perhaps through lack of adequate means) tends to become slovenly and to give a poor opportunity for the practice of good table habits. The financial difference between a table well laid, with clean plates, shining cutlery, and flowers, and the disorderly muddle which one frequently sees, is negligible ; the real difference is the essence of good education. Food and its handling before, during, and after a meal should be given a prominence, which is now completely lacking, in all schools, of whatever grade or character.

First, there is the choice of a menu: the children should be consulted—and taught. This is a lesson in relative food values and the importance of a balanced meal. The subject-matter can be linked with other educational material such as geography ; the seasonal choice of food, especially fresh fruits and vegetables ; and the economical selection of diet according to what the market provides. The elements of food purchasing is a practical lesson in arithmetic as well as in feeding.

In the second place, the preparation of food is a course of instruction in method, care, and cleanliness. It teaches children how to make use of the most valuable parts of certain foods, such as potatoes, thus avoiding waste in

wartime. Slovenly preparation of food in dirt and disorder begets disease and malnutrition. Good simple methods of preparation and cooking belong to the fundamental subjects of education for both boys and girls.

In the third place, the service of meals is at present almost wholly neglected as an educational subject. Yet what can be more important than these simple daily lessons in cleanliness, tidiness, correct eating, courtesy, and good manners? Slovenliness and guzzling would be checked; lack of consideration for others deliberately pointed out; noise, as distinct from reasonable conversation, prevented; and, in brief, elementary social qualities introduced by daily practice of a kind that would have a decisive influence on the whole outlook of the child.

Lastly, and not the least important, is the clearing up and cleaning up after a meal. One's mind turns to some recent examples actually witnessed, where pieces of bread on the floor and the generally dishevelled state of the tables were a disgrace. It is to be hoped that the revelations produced by the evacuation scheme will bring home to people of good will the immediate need to teach good habits to children. In wartime especially there is no more urgent lesson than the careful avoidance of waste. Every effort must be made to show children how much of the food left over from the preparation of one meal can be brought into use next day in an attractive form, and what should be preserved for humbler purposes. The protection of food, especially milk, from dust and flies must be demonstrated again and again until it becomes a routine.

2. Food and Nutrition

Malnutrition in childhood is difficult to assess; but it is known beyond doubt that large numbers of children suffer from varying degrees of defective nourishment. In most cases this is due not to gross lack of food but to faulty feeding. The commonest errors (which often lead to serious troubles) are insufficient vitamin intake and deficiency in mineral salts. The communal meal must therefore be scientifically prepared in such a way that the whole of the child's daily requirements of accessory food substances are supplied. One cannot rely on the vitamin content of meals taken at home in a working-class household. Milk is the best food for children, and there is no difficulty in finding a place for it in the midday meal. When this is done the provision of milk as a morning drink can be superseded.

3. Wartime Needs

Under war conditions all the arguments which can be brought forward to support a normal programme of communal feeding are strongly reinforced. There are two kinds of rationing—by food and by cost; and between the two the housewife will find it more and more difficult to provide for her children the right foods in the right quantities. The families whose incomes are near the poverty line cannot do it at all. Further, an increasing number of married women with children are finding places in factories, and are employed in work of national importance. The least the State can do for them is to see that their children are properly nourished. Our knowledge of how to organize communal feeding has passed far beyond the experimental stage, and the time has come for action. It is unnecessary to set out here the balance of foods which a communal meal must provide, or its content of vitamins and mineral salts; these have been worked out fully in Sir John Orr's recently published book, and they have been presented in a simple form by the British Medical Association. Many valuable books and pamphlets on wartime cookery have also been produced. The elements are well known and quite simple, and—what is more important—

the Ministry of Food is making sure of adequate supplies of essential foodstuffs.

The education authorities who are already carrying out the programme outlined in this note are increasing in number. Many good influences are at work and the gospel of nutrition is being widely spread through the skill and initiative of domestic science teachers and by officers of the Ministry of Food. Nevertheless there are backward areas, which serve to emphasize the need for universal provision. The fact that existing work in this direction has been so beneficial adds weight to the argument for transforming permission and encouragement into a definite obligation. It is our duty to see that wartime food is wisely chosen, carefully prepared, intelligently cooked and served, and put to the best possible use.

THE RED CROSS OVER BRITAIN

A year of intensive effort and adaptation is placed on record in the annual report of the British Red Cross Society. The Red Cross in this war has stood for the succour not only of fighting men but of civilians. It has expanded from a small peacetime to a large war organization, and the support of the public, including help from the United States, has been commensurate with its service. Its detachments number 2,828, with close upon 130,000 members and probationers. In 1940 the Society had 4,400 men and women serving full-time with the Forces, 5,365 women in the E.M.S. hospitals as members of voluntary aid detachments or the civil nursing reserve, 239 men and women on hospital trains, 7,240 men and women serving full-time and 28,500 part-time with A.R.P. posts, rescue parties, and mobile units, 3,000 men and women in auxiliary hospitals and convalescent homes, and just upon 2,000 with ambulances. The work done by women in providing hospital supplies and comforts almost defeats the statistician. The trained nurses department, which was set up immediately on the outbreak of war, has devoted itself to building up the trained nurses reserve; most of those mobilized are serving in convalescent or auxiliary hospitals, but a number have been seconded to the Ministry of Health for emergency duty. Two activities of the Society which are in full trim in peacetime as well as in war should not be forgotten. One is the Blood Transfusion Service. Last year the London service provided 1,395 donors, the lowest number for ten years. The diminution is due to the evacuation of patients from London hospitals. On an average each member during 1940 gave eleven transfusions. Eleven members have now given 50 transfusions, four 60, two 70, and two 80. Eighteen members of the committee of the Voluntary Blood Donors Association have a total of over 750 to their united record. This is represented as furnishing clear proof of the harmlessness of blood transfusion carried out over a period of years. The other activity is the Clinic for Rheumatic Diseases, Peto Place, where, in spite of evacuation, black-out, and air raids, 1,224 patients have attended and 35,367 treatments have been given. The results of treatment are rather less satisfactory than in previous years, owing to the larger proportion of advanced cases, the earlier ones being dispersed for various reasons; but environmental strain and shelter life are also likely to prevent optimum results. It is emphasized that after the war there is likely to be a notable rise in the incidence of rheumatic diseases, and therefore it is important to maintain the activities of the clinic at as high a level as possible.

G. Reysersbach, T. F. Lenert, and A. G. Kuttner (*J. clin. Invest.*, 1941, 20, 280) record their observations on an outbreak of influenza due to the virus recently described by Francis under the name of "influenza B" in a relatively isolated group of rheumatic children. The clinical symptoms were mild and remained remarkably uniform throughout the epidemic. There were no complications. Rheumatic recurrences were not precipitated by the outbreak of influenza. The characteristic laboratory finding was a relative leucopenia.

AWARDS FOR GALLANTRY AT SEA

The award of the M.B.E. (Civil Division) to Dr. L. F. TOGNERI is announced in a *Supplement to the London Gazette* dated July 9. The announcement reads as follows: "The ship was badly damaged by a U-boat, a torpedo struck her abaft the engine-room. The second engineer was trapped under a grating, with water rising fast. Chief Engineer William Skinner (awarded the O.B.E.) and Electrician Donald Mowat (awarded the B.E.M.), by the skilful use of crowbars, released the officer. The vessel took on a dangerous list to port and the master ordered all boats to be lowered, manned, and pulled clear. He himself remained on board with the chief engineer and the ship's surgeon, Dr. Togneri. These two officers helped the master to save the ship. As the weather was moderate and the vessel seemed to be holding her own, a number of officers and men returned on board and tried to get her in tow. Able Seaman David White (awarded the B.E.M.), who was the oldest member of the working party, showed special zeal."

AWARD FOR GALLANTRY IN CIVIL DEFENCE

The award of the George Medal to Dr. KENNETH EDWIN TAPPER, O.B.E., head of A.R.P. Casualty Services, Bromley, Kent, is announced in a *Supplement to the London Gazette* dated July 7.

The announcement reads as follows: "Dr. Tapper has on many occasions during enemy air attacks crawled under wreckage to search for and give treatment to injured casualties pinned down by debris. When people were buried beneath the wreckage of a German aeroplane and two houses Dr. Tapper gave medical aid to the victims while large unexploded bombs were removed. Dr. Tapper has shown great gallantry in his efforts to relieve suffering among air-raid victims."

Reports of Societies

TRICHINIASIS: MODE OF SPREAD AND MANIFESTATIONS

At a meeting of the Shaftesbury Military Hospital Medical Society on July 8, with Major-General F. CASEMENT, D.S.O., in the chair, Dr. PAUL BEESON, physician to the American Red Cross-Harvard Field Hospital Unit, read a paper on the mode of spread and manifestations of trichiniasis.

Trichiniasis, he said, was one of the few diseases the prevalence of which in Britain had markedly increased since the outbreak of the war. Before 1939 not more than fifty cases had been reported; since January, 1941, approximately 300 clinical cases had been notified, and it might be assumed that there were many more which were not recognized. Human beings acquired trichiniasis from eating pork. The illnesses in Britain recently were due to pork sausage prepared from local pork. It was probable that trichiniasis occasionally occurred in swine in this country as a result of their eating infested rats. The clinical manifestations were very variable, depending on chance deposition of parasites in different organs. Standard descriptions of the disease failed to emphasize this point. Gastro-intestinal symptoms occurred in less than half the clinical cases. Orbital oedema and muscle pains were usual manifestations. Subungual haemorrhages, present in some severe cases, constituted a striking and almost pathognomonic sign. Parasites in other parts of the body might produce signs suggestive of encephalitis, meningitis, pleurisy, pneumonia, or myocardial failure. The diseases which particularly required differentiation from trichiniasis were influenza, typhoid fever, bronchitis, gastroenteritis, acute nephritis, encephalitis, and meningitis. The first requisite in the diagnosis of trichiniasis was an awareness of its possible occurrence and of the many forms which it might assume. A differential leucocyte count was the best aid to early diagnosis; eosinophilia was almost constantly present during

the first three months of infestation. The parasite might be demonstrable in the circulating blood during the first three weeks or in muscle tissue after that time. The skin reaction to *Trichina* antigen was constant and quite specific, but it did not prove that an infestation had occurred recently, since it might be elicited years after. There was no specific therapy for trichiniasis at present.

Correspondence

Treatment of Burns

SIR.—I trust that all those concerned with the treatment of burns will have an opportunity to study your leading article in the *Journal* of July 12 (p. 53). Uncertainty prevails as to the choice of method of treatment, and fundamental principles are sometimes forgotten. This uncertainty has no doubt stimulated your timely reference to "confused counsel," "dissenting voices," and "sectarian division." Impartial workers feel, as a rule, that there is no place as yet for dogmatism, but that the experiences of the past should not be discarded with too much haste.

Pending Utopia, your article reminds us that "mortality rates must be the first criterion of success." The article quotes figures in support of those who still believe in coagulation with tannic acid as one of the best, if not the best, life-saving procedure. In a series of 1,913 cases of burns treated with tannic acid the mortality was 11.3%, while in a series of 1,369 treated by other methods the mortality was 24.5%. In a series of 809 cases treated by Glover and Sydow with tannic acid the mortality rate was 8.4%. They recommend the removal of the tan between the fifth and the eighth day. Treatment is continued with continuous Dakin's dressings.

I have had good fortune, in life saving, with the well-known combination of tannic acid and silver nitrate, and I can commend this application to others especially those who are working single-handed or under other adverse conditions. It was, I think, the serious complications that arose when tannic acid was applied to the fingers and face which led many to abandon the method *in toto*. Warnings, however, were sounded in the past against such applications, but they went either unnoticed or unheeded. In the *Medical Annual*, 1931 (p. 86), it is stated: "The resulting coagulum forms a very tight tourniquet and the finger-tips may slough off." Again in the same publication (1932, p. 84) attention is called to the fact that "the finger-tips should not be sprayed with tannic acid, as gangrene sometimes results, and tannic acid should be avoided also near the anal or oral margins."

"He wrongly accuses Neptune, who makes a shipwreck a second time."—I am, etc.,

Aberdeen, July 12.

W. I. DE C. WHEELER.

Envelope Treatment for Burns

SIR.—Several articles have appeared in the *British Medical Journal* on this method of treating burns, using a solution of electrolytic sodium hypochlorite with sodium chloride as irrigant. In the issue of July 12 (p. 46), after describing the method, Mr. J. W. Hannay ends by saying: "The great value of envelope irrigation is that one can be quite certain that in no case treated by it, with or without theatre cleansing, will anything more than mild infection occur. Can this be claimed for any other method?" Yes, certainly; this can be claimed for the method of hypertonic treatment with sodium sulphate "soaks" (that is, lint kept soaked with a saturated solution of Glauber's salt). Moreover, in a paper describing the practical applications of this method, which you published exactly a year ago (July 13, 1940, p. 53), I suggested that the true value of Dakin's solution in controlling sepsis (as of a number of other agents such as urea, insulin, partially evaporated pus, saliva, and sweat) lay in its hypertonicity over cycloplasm. I went more fully into the theory of the subject in a paper, describing over 1,000 cases, published in the *Lancet* (February 3, 1940, p. 216); but the point I wish

to make is that since experimentally Glauber's salt is proved to be much superior both osmotically and in diffusion to any other substance used for this purpose, and since I have shown that no "antiseptic" is necessary (vide *Lancet* paper above), should not this salt be the agent of choice for envelope irrigation? I will even suggest that the effect of sulphonamide drugs applied locally in a wound or burn is entirely hypertonic, except in regard to such of the substance as may be absorbed into the circulation.

The envelope idea itself seems quite good, but I consistently achieve similar results with a sheet of lint laid over a burn, kept soaked (under a sheet of oiled silk) with saturated sodium sulphate solution, and *not changed or otherwise interfered with* until it begins to stink (that is, after several days). This method can be applied to burns of all degrees not only by nurses in hospital but by totally unskilled relatives in the patient's home. The results are excellent; no sepsis occurs, the treatment is painless, tissue repair and epithelial growth are rapid, and the resultant scars are flexible and tough. I now treat all burns and scalds in this way from the beginning without tanning them.—I am, etc.,

York, July 17.

J. C. LYTH, M.B., B.S.

SIR,—In connexion with the articles describing the envelope treatment of burns (July 5, pp. 1 and 7) and your leading article in the *Journal* of July 12 (p. 53), the practice seems to have been adopted of describing dilutions of a basic 1% electrolytic sodium hypochlorite solution in terms of the solution and not of the active ingredient. Thus strengths of solutions of electrolytic sodium hypochlorite are described as "from 1% to 50%," whereas in fact what is meant is "from 0.01% to 0.5%" in terms of actual hypochlorite.

Might I suggest that it would be much clearer and less likely to lead to misunderstanding if the strengths of such solutions were indicated as actual sodium hypochlorite as shown above?—I am, etc.,

Harrow, July 16.

E. A. LUM, Ph.C.

Tuberculosis in Recruits

SIR,—The increasing attention which is being paid in this country to the mass radiography of recruits and industrial workers is raising certain new problems. Radiological detection of early tuberculosis has achieved a high degree of accuracy, but it must be followed by careful clinical assessment of activity if really valuable results are to be achieved. Confirmation of diagnosis by the finding of tubercle bacilli should be a primary aim in every case, and to this end gastric lavage, examination of faeces, and cultural methods will be needed in addition to the routine methods of sputum examination. Examination of the sputum by the fluorescent microscope is reported from America and elsewhere to give a higher percentage of positive results than do any of the standard methods of examination, but, so far as I am aware, this technique is not yet largely practised anywhere in this country. Dr. Gregory Kayne drew attention (July 12, p. 65) to the apparent discrepancies of results among sputum tests, and Dr. James Maxwell, in the same page, emphasizes that the finding of a positive sputum is not, in itself, evidence of activity.

Assessment of activity must depend to some extent upon prolonged observation, and for this purpose neither hospitals, sanatoria, nor dispensaries are entirely satisfactory. If these examinations are to continue to reveal between 1/2 and 1% of positive radiological findings, then special facilities should be provided for the observation and assessment of cases so detected. The adverse psychological effect upon a patient of the diagnosis of pulmonary tuberculosis is well known, as also is the social stigma attaching to the disease. Both these evils could, to some extent, be minimized if in suitable cases the patient could, from the very beginning, be assured that his disease is inactive and relatively harmless, both to himself and to other people.—I am, etc.,

London, W.1, July 17.

ALEC WINGFIELD.

SIR,—Dr. Gregory Kayne (July 12, p. 65) thinks that in our paper the fact was insufficiently stressed that recruits with undetected tuberculosis have been accepted into the Services. It is, of course, impossible, for obvious reasons, to publish the actual

number of men examined by Medical Boards, and therefore anything approaching a correct incidence of the disease cannot be calculated. It may be that between 1 and 2% of recruits are usually referred to tuberculosis officers, but to adopt a basic figure that may well vary 50% either way for the purposes of calculating an incidence rate would be quite unjustified.

Whilst we agree with Dr. Kayne that many men suffering from active tuberculosis have undoubtedly been accepted into the Services, we did not set out to prove this, but merely to indicate the results of the examinations of recruits actually referred to the tuberculosis officers in Wales, and from our findings we felt justified in recommending that "the indications for the reference of cases by Medical Boards to the tuberculosis officers should be comprehensive, and even then that cases of active or latent tuberculosis might be missed," and that "the finding of a substantial number of tuberculous recruits in Wales strongly supports the view held by most tuberculosis workers that all recruits should be subjected to a radiological examination." As Dr. Kayne suggests, a considerable proportion of sputum specimens from our out-patients are examined only by the direct method because fuller examinations, if necessary, are left until after the patients have been admitted to institutions.

Dr. Kayne points out that 73% of our diagnosed recruits were T.B.-negative as compared with 49% of our male new cases (other than recruits) aged 18 to 35, referred in 1940. The much higher percentage of T.B.-negative cases among recruits is due, in our opinion, to the fact that most of these men, unlike the ordinary male new case, had not suffered from such a degree of ill-health as to consult their own doctor, and that it is therefore reasonable to expect they would be earlier cases.

It is quite possible that the incidence of tuberculosis among the group of "discussed and approved pleurisy" is higher than among those men who had not previously been seen by a tuberculosis officer, but it is significant, nevertheless, that out of a total of 499 men who stated they had had a previous pleurisy, 116 (23%) subsequently developed pulmonary tuberculosis.

We are grateful to Dr. Kayne for his appreciative remarks and helpful comments.—We are, etc.,

Cardiff, July 15.

S. H. GRAHAM, M.B., D.P.H.
MOSTYN DAVIES, F.S.S.

First-aid Treatment of Injured Eyes

SIR,—Injuries to the eyes in an air raid are of very frequent occurrence; multiple foreign bodies in the conjunctival sac or embedded in the cornea from dust and debris, injuries from burns of the face and eyes, also from intense smoke, are the commonest. If a gas attack should occur there will also be mustard gas lesions of the eyes. These injuries are accompanied by very great pain and spasm and photophobia.

At a meeting of the Bristol Division of the B.M.A., reported in your issue of June 28 (p. 978), in a discussion on first-aid experiences in an air raid, one speaker said that of 250 casualties over half were eye injuries or burns. Another speaker referred to the large number of eye injuries and the urgent need for some anaesthetic for damaged eyes. Considering those statements and the extremely painful nature of eye injuries, it seems that some eye anaesthetic solution should be provided at first-aid posts. Such treatment would be as valuable as the injection of morphine for other injuries, for the following reasons: (1) to allay the very great pain in the eye; (2) to permit of efficient irrigation; (3) to allay fear and anxiety of the patient; (4) to prevent spasm and rubbing of the lids.

The *War Office Manual of Chemical Warfare*, 1939, states (of mustard gas cases) that cocaine should not be used to allay pain because it only exerts transient anaesthesia and tends to loosen corneal epithelium. It is true that cocaine used three or four times at short intervals or three times a day would lead to injury of the cornea, but would it do any real harm instilled only once? It would be valuable to have the opinion of leading ophthalmologists as to whether one application of cocaine drops would do any harm. One application would permit efficient irrigation and allay fear and pain until the patient got to hospital.

In the *Journal* of June 28 (p. 966) Dr. Dorothy R. Campbell of Coventry gave her experience of 100 eye casualties. She states that metycain and merthiolate ointment gave great relief.

without any ill effects on the cornea. I write to urge that a weak solution of cocaine (1%) or metycain and merthiolate ointment be supplied to first-aid posts for the efficient treatment and irrigation of damaged eyes. Not only would great pain be relieved but some eyes might be saved by more efficient treatment.—I am, etc.,

Deaf Hospital, July 13.

G. T. BIRDWOOD.

Flat-foot in Recruits

SIR.—We were interested to read the article by Captain R. T. Burkitt (June 28, p. 967) in reference to his treatment for flat feet in recruits. We have been in medical charge of training regiments for a considerable period, and we find that this is one of the most prevalent disabilities to be met with among recruits.

The men who have come under our charge have come directly from civil life, from a large variety of occupations, and have immediately to be put on an intensive course of drill and route marches for three months before being posted to their service anti-aircraft units. After dealing with recruits for some months we found such a large number of men complaining of flat feet that it interfered with the training programmes of the regiments. During this period in every case (all cases were of the first or second degree) we adopted the recognized method of raising the inner side of the boot with no success at all, and many complaints that the men found it difficult to do their marching with their boots altered in this manner.

We were thus compelled to try other methods, and we devised a support, to be worn inside the boot, consisting of a leather base with a bridge of sheet rubber supporting the arch beneath the leather and attached to it by adhesive plaster. This does not have the action of a metal support shaped to the normal arch of the foot, tending to push the arch upwards and so allowing the calf muscles to atrophy from disuse; but by being raised on the inner side, and having a certain amount of resilience, it appears to us that this pad tends to exercise and massage the arch of the foot during walking.

The men are instructed to walk on their toes as much as possible, and in severe cases they are given special physical training. Cases have been treated with exercises alone, but, as Captain Burkitt remarks, it is difficult to get the co-operation of the patient.

The routine in each case has been to fit a pair of pads made to the size of the foot and return the man to full duty. He reports after one week, and by this time most patients say that they have no pain in the feet, but that there is some slight aching in the calves. This is due to the strengthening of the muscles which support the arch of the foot. They report again at the end of four weeks and again at four-weekly intervals. Each successive examination shows improvement in the condition of the arch, and the men state that they can carry out full duty without pain. In uncomplicated cases of first- and second-degree flat feet we have so far had no cases of failure, over eighty cases being treated in this way, and as soon as the arch has returned to within normal limits the patient is advised to leave off wearing the pads for increasing periods until eventually he is able to discard them completely without causing a return of the pain. This usually takes from six to ten weeks from the date of fitting the pads.

In cases complicated by dropping of the transverse arch, hallux valgus, or other deformity, the reconstitution of the normal longitudinal arch takes much longer, but throughout this period we have had no case which has not been relieved by the wearing of pads. Cases which have been treated in this manner have never had to be boarded out of the Army, though a few cases complicated by other deformities have had to have their medical category lowered. By employing a good chiropodist who understands how to make these supports we have put back into training a large number of men who might otherwise have been useless for active work.

We are indebted to Lance-Bombardier Batson for his co-operation in the making of these pads, and to Lieut.-Colonel J. W. Lane, R.A.M.C., for permission to publish this letter.—We are, etc.,

S. B. SACHS, Capt., R.A.M.C.
L. GIBSON, Lieut., R.A.M.C.

July 8.

Economic Insulin Dosage

SIR.—In a letter in the *Journal* of April 5 (p. 535) Dr. R. D. Lawrence advocates the use of the more concentrated solutions of insulin on grounds of national and personal economy. The argument of national economy stands, in that bottles are saved by the use of the more concentrated solutions. The argument of personal economy, however, only extends to patients with diabetes who take large doses of insulin, as I realized the other day when a patient to whom I had recommended more concentrated insulin complained that it had cost her more in the course of a month. The reason is that the ordinary Record syringe, which most diabetics use, retains about 0.1 c.cm. of insulin after injection, and this quantity is wasted. The number of units wasted will, of course, be greatest with the strongest concentrations of insulin.

The most economic strength of insulin for various daily doses, calculated on the assumption of a daily wastage of 0.1 c.cm. and using 5-c.cm. vials, is given in the accompanying table. The difference in cost is not great in most cases, but a diabetic taking 12 units of P.Z. insulin a day will save 1s. a month by using 40 units/c.cm. rather than 80 units/c.cm. insulin. To many hospital patients this is a significant difference in cost.

Daily Dosage of Insulin	Most Economical Strength of Ordinary Insulin	Most Economical Strength of P.Z. Insulin
0-5 units	20 units/c.cm.	40 units/c.cm.
5-30 units	40 units/c.cm.	40 units/c.cm.
30-35 units	80 units/c.cm.	40 units/c.cm.
Over 35 units	80 units/c.cm.	80 units/c.cm.

—I am, etc.,

Radcliffe Infirmary, Oxford, July 13.

C. M. FLETCHER.

Diabetic Coma in Young Diabetics

SIR.—I am grateful to Dr. Wilfrid Oakley (July 5, p. 30) for his comments on my paper on diabetic coma. In Case 6, a severe case of coma in which Gerhardt's test on the urine was negative in the early stages, I could not with certainty detect acetone in the breath. His suggestion of testing the serum qualitatively by Brothar's test is a useful one. I quoted the case to emphasize the well-known but not sufficiently recognized fact that Gerhardt's test is occasionally negative in severe coma. I agree that the level of the systolic blood pressure is of great importance in assessing prognosis and treatment.

With regard to insulin dosage, it is very difficult to lay down rules and perhaps it was unwise to try. In my experience insulin dosage in coma, particularly in the early stages, tends to be too low rather than too high, and, perhaps by good luck, I have not yet seen a case which passed from diabetic coma into hypoglycaemic coma. The points that Dr. Oakley stresses, that if insulin is given two-hourly its action is a cumulative one, and that this tends to falsify blood-sugar readings, are very important, and these facts must always be allowed for in estimating dosage, particularly as the phase of recovery and possible hypoglycaemia is approached. Blood-sugar readings are, however, only a rough guide to progress, and must always be considered in relation to other factors, such as the clinical condition of the patient, the severity of any infection which is present, and the previous dosage and response to insulin in the past. Perhaps such clinical considerations have saved me from the pitfalls I deserved, and I appreciate Dr. Oakley's helpful criticism and warning about the risks of overdosage.—I am, etc.,

Cambridge, July 12.

LESLIE COLL.

Aggregation of Toddlers

SIR.—Your article (July 19, p. 91) regarding aggregation of toddlers needs consideration, lest it be misunderstood. "Commonplaces of medical knowledge" seem to belong to the beginning of the century, to confuse dangers of infection in the parasitic stage of infancy under 2 years with the toddler stage (pre-school) from 2 to 5 years, and to compare nurseries and crèches with infant schools. It is, however, the homes themselves which are the chief distributors of early infections.

"The expert direction of the medical officer of health" is mainly needed to comply with Acts of Parliament, and there are

many lacunae in his oversight, the care of the pre-school child being one of them. Ere the present popular awareness of this neglect, these conditions needing remedy may be well represented by a normal of ten years ago. The Registrar-General's reports for 1930-3 show an average of 1,780,000 children aged 2 to 5 years; of these 8,302 died annually. About three-quarters of these deaths were preventable. One group of zymotics—measles, whooping-cough, scarlatina, diphtheria—accounted for 2,572 deaths; the last, diphtheria, caused 835, every one of which should have been prevented. The diphtheria deaths among pre-school children are about equal to those at school ages. Here homes can certainly be traced as the source of about nine-tenths of the cases. Yet ten years later "expert direction" for immunization seems mostly concerned with school children (locking the stable door, etc.), neglecting the year-old infant, which intensive "infant care work" should look after. The immunization of this infant as regards public health is worth that of ten or a dozen school children. Diphtheria will certainly disappear when most children in the parasitic stage in the care of their mothers are immunized—but not till then, whatever is done with school children. The present prevalence of diphtheria represents the greatest failure of the first quarter-century of the Ministry of Health.

The next group—mainly due to poverty, malnutrition, and debility—had 2,660 deaths annually. Between 2 and 5 years 937 died from tuberculosis; and various respiratory infections, "pneumonias," accounted for 1,728 deaths. All this group probably would have been noticed early enough for treatment if nursery schools were universal; but to wait till ill-health needs the call of doctor or nurse, or drives the child to a clinic, is often to wait till the result is inevitable.

A third group consisted of 787 violent deaths. At that time motor vehicles sent a toddler to its death daily, and now this is more than doubled. Children at these ages will run and play wherever they can, and roads and streets are the most available spaces.

High mortality is not the only product. In 1,074 crippled children in London schools, 895 cases had originated before school age. Of those with tuberculosis half began between 2 and 5 years. "Damaged goods" are commonplace in school entrants. The primary school child, too, age for age, is several inches shorter and pounds lighter than the secondary school pupil.

Crèches and day nurseries should not be tolerated in any civilized communities except, like rationed food and clothes, under the inevitable compulsion of war. So far evacuation has given no certain or expected answer to these problems of infection, save a general increase in tuberculosis. Benefits to be evoked in reduction of the death and damage shown by the Registrar-General's figures would outweigh any effects of aggregation, but actually the few existing nursery schools have been more free from infections and debility than any comparable collections of children.

If money is to be spent on family allowances, its proper distribution would be directly in kind to the children themselves. From 2 to 5 years of age a nursery school should be the right of every child, a school to every 300 or 350 families. To provide plenty of space and freedom, where children can be fed, exercised, sleep, grow, and educate themselves into the membership of a child community, is a biological necessity. Here they can educate themselves more suitably than by any other means. They are not yet ready for teaching the conventional requirements of social intercommunication and accumulated knowledge, as interpreted by teachers and training colleges, and all such should be kept out. With a nurses' organization and a visiting doctor to detect the earliest signs of ill or disease, this nursery school is a substitute for the necessary natural education of family and fields, which urbanization otherwise precludes and few parents nowadays can be expected to provide, beyond the exceptionally rich.—I am, etc.,

Edinburgh, July 19

JAMES KERR.

SIR.—The urgent warning in your excellent annotation will, I hope, help to stem the tide of a major disaster. This matter has been the subject of our earnest attention and pressure on the authorities since the Munich crisis. The scheme has been recognized as an excellent one, but the underlying reason and necessity for it not being appreciated, no action has been taken and no

facility been given us to acquire the necessary accommodation. Indeed we have been challenged by various authorities that there is not the accommodation for the rational treatment of the mother and child. A survey in one county already crowded with evacuees seems to show that it is not so much absence of the type of accommodation required as lack of determination and courage on the part of the authorities to commandeer that accommodation with the same ruthlessness that is demanded by the fighting Services in securing what they need.

The health services in war demand the same autocratic generalship as any other force directed to the waging of the war.—I am, etc.,

INNIS H. PEARSE, M.D.

The Pioneer Health Centre, Peckham, July 19.

Hyperventilation Tetany in Tropical Climates

SIR,—I have read with interest Dr. Alec Wingfield's case report (June 21, p. 929). I find it difficult to accept his contention that the attack produced by hyperventilation and those which had occurred spontaneously in the Persian Gulf were one and the same thing. During a commission spent in those waters I had taken the opportunity to make some observations on the excretion of urinary chlorides. While these observations remain incomplete as a result of the advent of war and hence inconclusive, there was sufficient evidence to suggest that subclinical chloride deficiency was a common finding in the majority of any ship's company exposed for months on end to these trying conditions of tropical life. The inevitable and expected cases of "fireman's cramp" occurred and responded to the exhibition of chlorides. These cases are common, but probably represent a relatively small incidence among those suffering from the sub-clinical form.

I assume that in the case reported by Dr. Wingfield the hyperventilation tetany was induced under temperate conditions after the patient's return to this country. His chlorides may well have returned to normal—as is shown by the figures given. This, all the more, tends to discount any connexion between the aetiology of this attack and the previous spontaneous ones in the Persian Gulf. The latter have the basis of strong presumptive evidence for the assumption that they were due purely to chloride deficiency, while the former is invariably associated with an alkalaemia. The fact that Dr. Wingfield was able to induce tetany by hyperventilation does not identify this phenomenon with the one occurring under tropical conditions.—I am, etc.,

W. J. FORBES GUILD, M.D.,

Surgeon Lieutenant-Commander, R.N.

June 27.

Suture of Cut Flexor Tendons

SIR,—We wish to refute the numerous assertions made in your columns that suture of a flexor tendon which has been cut within its sheath is invariably unsuccessful. Within the last year we have dealt with ten cases of cut flexor tendons of the fingers, all of which occurred within the flexor sheath. Five of these cases can be classed as successful—that is, they have over 75% function. Five cases were immediate suture and five were delayed. Of the five treated by immediate repair, three were successful and one had 50% function. The remaining case developed infection and a stiff finger. Of the five cases treated by delayed suture, two were successful, one had 30% function, and the remaining two were failures. Our routine treatment has been as follows: (1) Avoidance of any cleansing processes (after the Böhler technique). A blood-pressure cuff is used for a tourniquet. (2) Painting the digit with iodine or flavine and spirit up to the wound edges. (3) Complete excision of wound. (4) The original wound is enlarged in the longitudinal axis of the finger, the proximal incision being made to one side of the mid-ventral line, the distal incision being made on the opposite side of the finger, so that one then has a Z-shaped incision. (5) The tendon is exposed and a stay stitch is inserted to maintain the tendon in apposition. (6) If the wound is dirty or the tendon ends frayed, the ends of the tendon are freshened. (7) The Sterling Burnell suture of fine silk is then used and the stay stitch is removed. No attempt is made to repair the sheath, and the skin is sewn up with interrupted stitches. (8) No splint is used, and the following day slight active movements are

started. (9) If the wound is grossly contaminated it is excised and the tendon left for delayed suture.

A series of tendon sutures which has produced 50% good results is, we feel, sufficient to confute the advocacy of those of your correspondents who practise immediate amputation. The efficacy of the treatment can be determined within seven days, and if necessary amputation can then be carried out. The use of the fingers is of such vital importance that to amputate without first attempting to repair the tendon is, we feel, an unjustifiable procedure.—We are, etc.,

Sulphonamides and Sulphur

SIR.—With reference to your issue of October 12, 1940 (p. 468), I notice an article by Mr. E. J. Radley Smith showing evidence that the danger of combining sulphonamide treatment with sulphur ingestion by any means is probably greatly exaggerated. I have also been in agreement with this view since I was working at a maternity hospital in Nigeria. There many of the cases were patients in *extremis* from obstructed labour and septic interference by native doctors. The dead foetus had to be extracted piecemeal, and sulphanilamide was immediately instituted. It was only after several weeks that I realized that these patients were also being given large doses of mag. sulph. as part of their after-treatment to diminish lactation. It was a custom of the nursing staff to give the salts automatically after a stillbirth or neonatal death without medical prescription. I had not noticed any cyanosis or symptoms attributable to such a condition, which is, of course, obscured in the African. There was a high mortality among these patients, and I have no figures to present; but I remember thinking it wiser not to interfere with the teaching of the midwives, who, being African, are muddled by alterations in routine. It would be interesting to know if controlled experiments on animals have been made which substantiate the idea that sulphonamides and sulphur are dangerous together.

The reference in your *Journal* is very old, but the numbers have followed me many miles and then have had to wait for a convenient opportunity for me to read them. The subject cannot be out of date, at any rate.—I am, etc.,

Kenya, May 6.

A. D. HODGES.

Crush Injuries

SIR.—With reference to Sir Leonard Hill's letter (March 29, p. 491), in which he attributes the renal failure in so-called "crush" injuries (accompanied by shock) to anoxia, I beg to draw attention to the extracts given below from Halliburton and McDowall's *Physiology* (1937), which make clear the vital importance of an adequate oxygen supply for healthy kidney function. Shock, it may here be recalled, has been defined by McDowall (*Journal*, 1933, 1, 690) as "the state resulting from a fall in arterial blood pressure, which if severe may result in death from oxygen want."

"The phenomena of the collapse of the circulation in shock may thus be summarized (after Muir, *Textbook of Pathology*, 1936):

During shock the capillaries of the skin and abdomen are tightly constricted, while those of the skeletal muscles are dilated and the blood stagnates in them. Blood pressure in consequence falls. The blood vessels of the body in general, and particularly the peripheral arteries and veins, are constricted in an effort to maintain blood pressure (McDowall, loc. cit.).

Abnormal permeability of the walls of the dilated capillaries then develops from want of oxygen (Bayliss, Spec. Rep. Ser. Med. Res. Com., 1919, London, No. 25), and an increased amount of blood plasma passes out of the circulation into the tissues, with the result that the blood becomes concentrated and the blood volume is diminished. The amount of blood reaching the right side of the heart thus becomes seriously reduced, and generalized oxygen want or asphyxiation of the body cells results."

Regarding the increased permeability of the capillaries in shock Bayliss writes:

"If this increased permeability has not reached too high a value or not been present for too long a time, recovery is possible.

... It is evident, then, that the state is capable of return to normal if not too serious. The renewed supply of oxygen restores the necessary impermeability to colloids." Regarding collapse of the circulation as observed in experimental animals, Bayliss states that if they are treated shortly after onset recovery takes place, but "if left for two hours or more ... recovery is impossible" (owing to permanent damage of the capillary endothelial cells).

Regarding renal function Halliburton and McDowall write:

"One fluid, the arterial blood, enters the kidney; two fluids, the venous blood and the urine, leave it. Both of these fluids are different in composition from arterial blood. ... We know that it is not possible to convert any fluid into two others, each of different composition from itself, without an expenditure of energy which must come from somewhere outside the fluids themselves. In the kidney, as in other secreting glands, this energy comes from the cells of the organ and the pressure of the arterial blood. The secretion of urine is therefore the result of work done by the kidney. The quantity of work done may be measured within certain limits, and the energy transformed by the kidney may be estimated in several ways). ... Estimations have been made of the amount of oxygen used by the kidney in secreting urines of known concentration. This oxygen may be taken as a measure of the amount of energy used by the organ. ... The practical importance of these considerations ... lies in the fact that the expenditure of energy involves combustion, and combustion demands oxygen. For this reason an efficient supply of oxygen is essential to ... healthy kidney (function)."

With reference to the secretory power of the glandular epithelium of the kidney tubules, Halliburton and McDowall state:

"In frogs the glomeruli can be cut out of action by ligaturing the renal arteries. The kidney is then supplied by the renal portal vein, a vessel which goes to the tubules only. If urea is then injected under the skin, secretion of urine occurs, which, though scanty in amount, is peculiarly rich in urea. Urea, therefore, in the frog is secreted by the epithelium of the tubules. In order to obtain this result the kidney must receive sufficient oxygen for the maintenance of the functional activity of its cells. As the arterial supply is cut off by ligature of the renal arteries, this must be accomplished ... by keeping the frog in an atmosphere of pure oxygen."

J. WALKER TOMB.

Pelvic Abscesses

SIR.—Mr. Harold Dodd's article on pelvic abscesses (May 3, p. 667) gave an excellent description of the diagnosis of this condition. The rectal symptoms and the changes in the tongue were stated with particular lucidity, and should be a valuable guide towards diagnosis of pelvic abscess.

Mr. Dodd does not, however, mention a symptom which is commonly present—namely, bladder irritation. My experience is limited, but in nearly all cases I have seen, frequency of micturition is a symptom which occurs as early in male patients as rectal irritation, and, in conjunction with the latter, in cases of appendix abscess is one of the most valuable signs by which a diagnosis of pelvic abscess can be made. The suspicion of "pus somewhere," together with the temperature chart and the signs of rectal and bladder irritation, makes the diagnosis of pelvic abscess almost certain even without a digital examination of the rectum.—I am, etc.,

Kailahun, Sierra Leone, June 9.

Post-herpetic Paralysis

SIR.—With reference to recent correspondence on post-herpetic paralysis, presumably due to the virus of herpes zoster and chicken-pox causing a diffuse infection of the spinal cord, I am describing the following case in a man aged 61 who was admitted to the Royal Hospital, Wolverhampton, recently with wasting of hand and shoulder muscles and gross trophic changes in the skin of the hand. Seven months before admission he had an outbreak of shingles, passing down the outer side of the left arm and forearm and into the palm of the hand. Following this he complained of severe pain in the arm, which gradually became weaker and wasted, and developed trophic changes in the skin.

On examination he held the arm in a condition of adduction at the shoulder, with the elbow flexed as in hemiplegia, but with a wrist-drop. The arm was very painful to touch; the left hand showed marked trophic changes; the skin was very thin, shiny, and of a mauvish tint, and over the terminal phalanges it was

adherent to the bone. There was marked wasting of the small muscles of the hand and of the deltoid, pectoralis major, and scapular muscles; all these muscles showed a fine fibrillary tremor. Associated with the wasting was a marked loss of power of all movement, and the tendon jerks were absent. Sensation was normal, and in other respects there was no abnormality in the central nervous system. Blood pressure: 150/70. Lumbar puncture: clear fluid under normal pressure, protein 0.04%, otherwise normal. Wassermann: negative. X-ray examination showed osteo-arthritis of the cervical spine "consistent with his age."

He has been put on a course of vitamin B₁ injections, and the arm has been treated as in poliomyelitis with splinting, massage, and active movements. It is hoped that, like the case reported by Dr. R. G. Abercrombie (May 24, p. 778), he will get a good recovery. After just over one month's treatment he is now recovering rapidly. He can now flex his fingers into the palm, and also raise the arm above his head; there is now no wrist-drop. The reflexes are also present, though still rather sluggish.

This case presents the unusual features of (1) marked trophic changes of the skin, (2) wasting of both shoulder and hand muscles, and (3) fibrillary twitchings. The accounts of recent cases in the *Journal*, however, with similarity in case history, age, and associated osteo-arthritis, leave little room for doubt that in this man the herpes was the cause of the trouble.

Once a new clinical entity is described further cases are usually soon found. It will be interesting to hear of them and of prognosis with treatment in a series, and perhaps there may be some new light shed upon the obscure aetiology of the motor neurone diseases?—I am, etc.,

Wolverhampton, July 10.

K. W. G. HEATHFIELD, M.B., B.S.

Three Unusual Rheumatic Cases

SIR,—On January 20 of this year a poor-class red-haired boy of 7 years came under my care in the country suffering from rheumatic fever. The illness was severe, both knees, one wrist, and the sternoclavicular joint being affected at different times. Cardiac symptoms were alarming, but the whole condition was so well controlled with aspirin that the boy made an excellent recovery up to a point in six weeks. While the knee-joints became freely movable and painless, it was obvious that the fluid swelling had extended down the front of each tibia over its upper third. As symptoms that the fluid might be purulent became manifest sulphonamide treatment was instituted with good results. Large quantities of pus at different times were discharged from both legs without upset or pain. The health of the boy remained comparatively good, appetite enormous, spirits excellent.

On June 7, circumstances for the first time permitting, he was radiographed and seen by a surgeon with regard to the minute sinus on the front of each tibia. X-ray examination showed nothing that could not be felt with the fingers—a considerable amount of periostitis. There was fluctuation around one sinus, and the boy had some fever and a slight cough. One week later, on admission to the children's ward for operation, he became unpopular by whooping on his first night. Hurried home thirteen miles with a temperature of 102°, the boy passed uneventfully through his attack of whooping-cough, and is now running about in a remote country district with a shilling-sized crust on the front of each tibia. This is perhaps a case of streptococcal osteomyelitis.

On June 3 of this year I attended a woman of 50 with erythema nodosum (her second attack in three years). In addition to this much more severe attack, the spots extending above the knees, there was herpes on the neck on one side, attributed by the patient to putting round the neck a cold compress for a sore throat.

On June 30 I attended a young married woman who complained of stiffness of the ankles and large spots on the front of the legs. She had typical erythema nodosum. On July 2 herpes appeared on both sides of her neck, extending from the posterior triangle to the mastoid process. I presume erythema nodosum is still recognized as having a rheumatic origin.

In this stagnant backwater of England 1941's increased prevalence of rheumatic conditions is attributed to the persistent east wind.—I am, etc.,

Harlem, Northumberland, July 14

RICHARD BILL, M.B., Ch.B.

Medical Man-power

SIR,—Owing to the spurious shortage of medical man-power, consequent on bad distribution of existing personnel and uneven division of work between civilian and Service requirements, as shown by recent correspondence in the medical press, I would like to make the following suggestions.

(1) That all medical men of military age should be called up in rotation in age groups for a specified period of military training. When this has been completed, those who are really needed can be absorbed into the Services and the remainder allowed to return to civilian work, where they can continue until definitely required. In this connexion the wastage resulting from the calling up of key men in hospital positions and delegating them to relatively inferior positions with little work in the Services is apparent.

(2) The apportionment of medical work as between civilian and Service requirements needs to be immediately surveyed. At the present time a high percentage of Service patients are treated in civilian hospitals, and there is a feeling that this could be extended outside hospital practice, so that, for example, general practitioners who have received a period of military training and have returned to civilian life could undertake Service duties in addition to their civilian commitments, and in this way release a number of full-time Service personnel in this country.

Edgware, July 12.

A. A. CUNNINGHAM.

Physiotherapy

SIR,—I have read with much interest Dr. L. D. Bailey's letter (June 28, p. 986) summing up the various points which have been brought forward in recent correspondence. I, too, have the honour of serving hospitals in the Emergency Medical Service, and among these hospitals there are some designated Orthopaedic Centres, but a variety of other cases, medical and surgical, are treated in the wards and physiotherapy departments of these centres.

I agree with Dr. Bailey that the adviser in physiotherapeutics must have a wider outlook than that conveyed by "orthopaedic physician." Whether the case is orthopaedic or plain medical or surgical, the physiotherapeutic adviser has to treat the patient as a whole and must have a comprehensive knowledge of disease, as well as of physiology and physiotherapy.

There is much diversity of opinion among some physicians and surgeons as to benefits derived from physiotherapy, and there is a crying need for clinical research in collaboration with physicists and physiologists, so that physiotherapy may be established on a scientific and clinical basis and confidence encouraged in the doubting members of the profession; otherwise this important branch of medicine is bound to remain linked with ideas of magic and quackery.—I am, etc.,

London, W.

N. I. LANCKENAU, M.D.

Fire-bomb Injuries

SIR,—Since writing the letter on protecting eye-shields, which you published on July 19, I have seen a patient who had received a deep wound in the elbow, severing the ulnar nerve, with consequent changes in the ring and little fingers and constant and severe pain in the other fingers. He was dealing with a fire-bomb, using the lid of a dust-bin as a protection. He told me that a friend of his tried to put out one of these bombs by putting the lid of a dust-bin over it and standing on it. The resulting explosion injured his foot.—I am, etc.,

Birmingham, July 20.

T. HARRISON BUTLER, F.R.C.S.

The Department of Health for Scotland has issued E.M.S. Memorandum No. 7 on the first-aid treatment of burns. The memorandum was prepared by a committee under the chairmanship of Sir John Fraser. There are four pages of text and a cover, on the inside of which, facing page 4, is a drawing of the human figure with indications of suitable treatment for different parts of the body. The memorandum (price 2d.) can be obtained at H.M. Stationery Office or through any book-seller.

Obituary

F. B. CHAVASSE, M.C., D.M.

Lecturer in Ophthalmology, University of Liverpool

We regret to announce the death on July 5, as the result of a motor accident, of Francis Bernard Chavasse, the well-known Liverpool ophthalmic surgeon, who came of a family which has distinguished itself in the Church, in medicine, and on the field of battle. His grandfather was Thomas Chavasse, F.R.C.S., and his father, the Right Rev. Francis Chavasse (afterwards Bishop of Liverpool), was Principal of Wycliffe Hall, Oxford, at the time of his birth on December 2, 1889. His brother, Captain N. G. Chavasse, won the Victoria Cross and bar in the last war, and the Gold Medal of the British Medical Association was awarded to him posthumously. Another brother, the Right Rev. C. M. Chavasse, is now Bishop of Rochester.

Bernard Chavasse went to school at Liverpool College, then spent five years at Balliol College, and entered the University of Liverpool as a final-year medical student. He took the English Conjoint qualifications in 1915, graduated in medicine at Oxford in 1919, and obtained the D.M. and M.R.C.P. in 1920, and the D.O.M.S. soon afterwards. He had a brilliant career at Oxford, winning the Theodore Williams scholarship in anatomy and in physiology and an honorary Brackenbury exhibition at Balliol, and graduating with first-class honours in physiology in 1912. At Liverpool he won the Derby exhibition in clinical medicine and the University exhibition in clinical surgery in 1915. During the last war he served with a temporary commission in the R.A.M.C., first as regimental M.O. of the 1st City Battalion, King's Liverpool Regiment, for nearly four years, then as officer-in-command of the 97th Field Ambulance, and lastly as medical officer at G.H.Q. He was awarded the Military Cross for gallantry in action. His paper on a method for the immediate treatment of fracture of the femur on the battlefield at the site of the casualty published in the *British Medical Journal* of October 5, 1918, was reprinted at the wish of many readers in our issue of January 6, 1940.

Chavasse's main interest was in diseases of the eye. He had been clinical assistant at the Oxford Eye Hospital, in the ophthalmic department of the London Hospital, and at Moorfields. He was appointed lecturer in ophthalmology at the University of Liverpool in 1923, and became full surgeon to the eye department of the Liverpool Eye and Ear Infirmary after working for some years as assistant surgeon and honorary pathologist.

Dr. Charles J. Macalister writes:

Death is a great awakener of memories in the living, and the passing of Bernard Chavasse has aroused many recollections concerning him and his collaterals. The very house in which he lived and worked and wrote his book has associations with the history of ophthalmology as a specialty, for in it dwelt and practised Edgar Browne (the son of "Phiz"), who, like other early specialists, began his career as a general practitioner. I venture to recall one or two impressions concerning Chavasse, who was known to me from the period of his school days. As a youth, certain characteristics presaged those of later years in that he was serious minded and possessed of a thoughtfulness of purpose which led to his giving methodical and concentrated attention to whatsoever work or play he might have in hand. When writing his book or engaged on any professional subject which might be interesting him at a given time, it was quite difficult to get him away from it until it was completed: in fact, whatsoever he undertook to do he did it with his might. The same trait dominated his play, which, after his school days, mainly consisted in sailing. Many incidents illustrative of his methodical ways of doing things might be quoted: they were in evidence domestically and professionally, but, if particular examples are to be cited, we must turn to two sad episodes which fell to his lot during the 1914-18 war. The first of these was when he made an attempt—alas! unsuccessful—to discover his missing

younger brother Aidan in July, 1917, which involved a search associated with danger over the domains of No Man's Land. The second incident was his investigation of the circumstances in which his brother Noel died of wounds on August 4, 1917. His father, of beloved memory, sent me a copy of Bernard's letter dated August 8, 1917, which gave a lucid account of the whole occurrence. It ended up with the words, "With all the sorrow of it one does feel very proud of him. He was behaving very gallantly when, already wounded, he received his fatal wound, and he never lost his courage during his last hours. This is not the snuffing out of a beloved nonentity but the death of a man of valour who was also a man of God." In his memorial address at the Church of St. Peter-le-Bailey, Oxford, on July 10, the Dean of Liverpool (Dr. F. W. Dwelley) related an incident throwing light on the religious aspects of Bernard Chavasse's life, and there is ample evidence that he was, like other members of his family, a valiant man who will be remembered for his gentleness and generosity by people representing every section of the community, including those to whom he ministered in the hospital with unbounded skill and kindness.

DOUGLAS STANLEY, M.D.Ed., F.R.C.P.Lond.

Emeritus Professor of Pharmacology and Therapeutics in the University of Birmingham

It is with great regret that we have to record the passing of Dr. Douglas Stanley at the Manor, Feckenham, Worcestershire, on July 5.

He graduated at Edinburgh in 1889 and took the M.D. with first-class honours and the gold medal five years later. After holding resident appointments at the Royal Infirmary he went to Birmingham as resident pathologist at the General Hospital in 1893, and the rest of his life was spent in that city. After an association with the General Hospital of about three years he "crossed the floor of the House" and joined the staff of the Queen's Hospital. Later he was elected to the Children's Hospital. In 1909 he became professor of pharmacology and therapeutics at the University of Birmingham. After Dr. Stanley had reached the age of retirement from Queen's Hospital he was offered the post of visiting physician to the Hallam Hospital, West Bromwich, a post which he held until the time of his death. He joined the British Medical Association in 1890, was honorary secretary of the Section of Pathology at the Sheffield Annual Meeting of 1908, and vice-president of the Section of Diseases of Children at the Birmingham Meeting of 1911.

It is but little exaggeration to say that Stanley devoted his life to teaching the students of the Birmingham Medical School: and just as his own profound medical knowledge was based on observations in the post-mortem room, so, too, was his teaching. A clinical clerk who failed to follow a fatal case from the ward to the post-mortem room would only be guilty of this sin of omission once during his six months' clerkship. Stanley was a great teacher: his own knowledge was built on clinical observation and morbid anatomy, and he had the rare gift of being able to impart his knowledge to others. He was often sarcastic, and his sarcasm could be biting, but "D. S." as he was affectionately called, had a great following among the students of the school. Stanley's interests were not confined to the bedside or the laboratory: he devoted much time to hospital administration, and for many years served on the management committees of both the Queen's and the Children's Hospitals.

To say that Stanley was pugnacious would possibly be to give a wrong impression of the man, but he was a fighter, a keen fighter, but always a clean fighter. He had strong opinions and never hesitated to express them; there was no sitting on the fence, and whether at a hospital board meeting, a discussion before a medical society, or in the columns of the Press, he said what he thought, and even

which he was a passenger was sunk. Dr. Marks was on a raft for two days and at the end of that time died from exposure. Thus ends the short story of one whom all his friends had hoped would ere long occupy a prominent position in the profession which he had chosen and to which he was so admirably suited.

The tragic and untimely death of HARRY DRYERRE (writes a colleague) has been a heavy blow to his numerous friends and colleagues in the Royal Air Force. He achieved that uncommon combination of academic knowledge and practical clinical acumen which undoubtedly would have in later years ensured a brilliant career in medicine. Not only did his unbounded energy and vitality enable him to keep abreast of the ever-increasing flood of medical literature, but he also had the critical faculty to sift the grain from the chaff. Apart from his professional ability, his delightful personality made him a true friend both to his fellow workers in the medical branch of the R.A.F. and to his numerous patients in other branches of the Service.

Dr. ARTHUR ROBINSON, who died on July 3 at his home at Ilkley, aged 72, had practised for many years in Halifax, and was honorary secretary of the Halifax Division of the British Medical Association in 1922-4. A student of the Leeds Medical School, he took the licence of the Apothecaries' Society of London in 1899, and served in the Boer War as a civilian surgeon attached to the South African Field Force; after being invalided home he began general practice in Halifax. Dr. Robinson was a keen supporter of the Yorkshire County Cricket Club, and a few years ago accompanied the Yorkshire team when it toured Jamaica.

"R. B." writes: The death of Major JAMES ROUSE, R.A.M.C., while on active service in Crete will be deeply mourned by a very wide circle of friends. As an anaesthetist at Worthing he was on the staff of the Hove General, the Royal Sussex County Hospital, and the Worthing Hospital. He was an extremely competent and calm anaesthetist who always kept his technique abreast of modern developments. He was an untiring worker and would come many miles in order not to miss his hospital list. Apart from his professional duties, he was a keen student of horse-racing, and he often made time to attend the big races of the season. He was a bridge player of quite exceptional merit, while one of my last recollections of him is watching him make a delightful break of 45 at snooker.

We regret to announce that Dr. JAMES HUSSEY of Farnham died on July 4 after an operation. He had been chairman of the Guildford Division of the British Medical Association in 1937-8 and still more recently president of the Surrey Branch. James Hussey was an outstanding student of his time at St. Bartholomew's Hospital, which he entered in 1891 with a preliminary science exhibition; this was followed by a junior scholarship and a senior scholarship, and three years later he won the Brackenbury scholarship in medicine and the Lawrence scholarship; he was also president of the Abernethian Society. In 1896 he qualified M.R.C.S., L.R.C.P. and took the M.B. degree of London University, and proceeded M.D. in 1898, after serving as house-physician at St. Bartholomew's and bacteriological assistant in the laboratories of the English Royal Colleges. Dr. Hussey had practised for many years at Farnham, and at the time of his death was the senior member of a partnership of four and consulting medical officer to the local hospital. He will be greatly missed by his colleagues of the Surrey Branch and by the many patients in Farnham and its neighbourhood whom he attended with so much skill and human sympathy.

The following well-known foreign medical men have died: Dr. BERNHARD WIKI, formerly professor of therapeutics at Geneva, aged 73; Dr. ALEXANDER WESTPHAL, formerly professor of psychiatry and director of the psychiatric clinic at Bonn, aged 78; Dr. HECTOR CRISTIANI, formerly professor of hygiene and bacteriology at Geneva, aged 78; Dr. HANS SCHAEER, senior surgeon to the University surgical clinic at Zurich, aged 40; and Dr. ERNST FANKHAUSER, a Berne psychiatrist, aged 72.

An appreciation of the late Dr. Sidney Davies (of whom an obituary notice was published in our issue of June 14) has appeared in the *Kentish Independent* of July 4. The writer of this, Mr. C. H. Grinling, Redroofs, Peaslake, near Guildford, Surrey, has some reprints and would send copies to any readers interested in Dr. Davies' life and work.

The Services

EFFICIENCY DECORATION, TERRITORIAL ARMY

The King has conferred the Efficiency Decoration of the Territorial Army on Lieut.-Colonel G. G. Talbot, Majors (Temporary Lieut.-Colonels) T. C. McKenzie and G. M. Lewis, and Major A. Angus, R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

ROYAL NAVY

In an Admiralty casualty list, published on July 18, the name of Surgeon Lieut. VINCENT JOSEPH REDMOND SHERIDAN, D.S.C., R.N., is included as "Missing, Presumed Killed," in H.M.S. *Kelly* off Crete. He was born in May, 1914, the second son of Dr. and Mrs. John Sheridan of Barnsley, was educated at Stonyhurst College and at the University of Edinburgh, where he graduated M.B., Ch.B. in 1936. He entered the Royal Navy as surgeon lieutenant in the following year and, after a course at Chatham, served on the China Station, first in the *Mantis* and then in the *Sandpiper*, returning to England in March, 1940. A *Supplement* to the *London Gazette* dated January 1, 1940, announced that the King had awarded Surgeon Lieut. Sheridan the D.S.C. "for services in the Sino-Japanese conflict."

Wounded or Injured

Probationary Temporary Surgeon Lieut. Paul Tudor Merlin, R.N.V.R.

Probationary Temporary Surgeon Lieut. Michael Noel O'Riordan, R.N.V.R.

ROYAL ARMY MEDICAL CORPS

Captain ROBERT THOMSON EASTON died in May of wounds received on active service in the Middle East. He was educated at the University of Aberdeen, where he graduated M.B., Ch.B. in 1927. He had held the posts of house-surgeon and house-physician at Oldham Royal Infirmary and assistant resident medical officer at St. Mary's Hospital for Women and Children, Plaistow. Before the war he was in practice at East Ham. He leaves a widow. He had been a member of the British Medical Association since 1928.

Missing, Believed Prisoner of War

Lieut. Richard Maurice Solomon.

Prisoners of War

Acting Colonel Harold Cane Godding, M.C.
Temporary Lieut.-Colonel Ailwyn Herbert Clarke, M.C.
Temporary Major John Leslie Martin.
Lieutenant Oliver Ive.

Universities and Colleges

UNIVERSITY OF LONDON

COMBINED HOSPITALS UNIVERSITY ENTRANCE SCHOLARSHIPS
As a result of the examination held for the University Entrance Scholarships, offered by St. Bartholomew's Hospital Medical College, Guy's Hospital Medical School, and St. Thomas's Hospital Medical School, the following awards have been made:

St. Bartholomew's Hospital Medical College.—P. R. Westall, Queen's College, Cambridge, scholarship; P. P. H. Schmidt, St. Catherine's Society, Oxford, exhibition.

Guy's Hospital Medical School.—R. E. Irvine, King's College, Cambridge, scholarship; J. M. Thomas, Gonville and Caius College, Cambridge, and D. P. Wheatley, Emmanuel College, Cambridge, (equal), exhibition.

St. Thomas's Hospital Medical School.—G. T. Aked-Davies, St. John's College, Oxford, scholarship; N. K. Connolly, King's College, Cambridge, exhibition.

UNIVERSITY OF SHEFFIELD

At a meeting on July 11 the University Council received the resignation of Mr. T. B. Mouat of the post of Honorary Lecturer in Surgery, and accorded its thanks to Mr. Mouat for his services to the university.

UNIVERSITY OF DUBLIN

SCHOOL OF PHYSIC, TRINITY COLLEGE

The following candidates have been approved at the examinations indicated:

M.D.—A. Dolphin, E. G. Fox, Sheila Kenny, M. Toohey, J. D. Whiteside.

FINAL MEDICAL EXAMINATION.—*Medicine, M.B.*: †G. S. Prince, †Maude F. P. Bigger, †G. B. Gibson, †Gladys M. Byers. †Elizabeth

D. L. Simpson, †T. A. H. Black, †S. T. McCollum, †Helen S. Watson, †Mellanie P. Crowe, C. R. Griffin, D. J. Naughton, J. P. Walsh, N. J. Anderson, H. Lesselbaum, A. J. B. McFarland, J. P. Heame, P. Medical Notes in Parliament

Winter Milk Supply: Lord Dawson's Warning

In the House of Lords on July 15, Viscount DAWSON of PENN called attention to the prospective shortage of milk and eggs, and the dangers to the health of the people liable to result therefrom. He said that while, during the summer months, the amount and variety of food available were adequate, the prospect for the coming winter was less secure and in certain respects might easily cause concern. It was disquieting that the production of milk, which was the priority food, should be progressively declining. Dealing with the difficulties which the dairy farmer had to face, Lord Dawson said that the unskilled worker was less careful in his cleanliness, less careful of his hands and churns, and the cows' udders were less well cared for; as a result, udder disease was more prone to break out. The remedy was so far as possible to call back the skilled agricultural workers and to set up an intensive course of three months for intelligent girls who, under modern education, would soon learn how to care for the cow and milk production.

The absence of skilled handling had also resulted in serious wastage of milk owing to the milk having gone sour. The collecting stations should quickly get down to efficient pasteurization and the local health authorities should be more close in their inspection of the collecting stations. The dairy herds must have all the food they required if the output was to be maintained this winter. Monotony in food should be avoided, and milk and eggs would enable that to be done, especially in the winter months. We must have more eggs, which were valuable not only for food but for their culinary quality.

The DUKE OF NORFOLK said that the Ministry of Agriculture, without a great deal of help from the medical profession, had encouraged for some years past the dairying branch of agricul-

ture. Dairy herds were increasing to-day, and the Ministry was doing all it could to induce farmers to employ women in the cowhouse and cowshed. At present there was enough milk in the country to meet the demand, but in the winter there might be some slight shortage. He hoped that, over and above the amount of milk necessary for the health of the nation, there would be no undue increase in demand. Everything was being done to maintain the production of milk.

LORD WOOLTON said that fewer people were suffering from malnutrition now, at the end of the second year of war, than in the days of peace. That was apparently due to Government policy in securing not only adequacy of supplies of food but of distribution according to people's needs. Many people were now more adequately fed than before the war began. We could look to the future with much confidence. As a result of the generous provision which the United States was making and with the help of New Zealand, he hoped to be able to remedy the defect of lack of variety to an increased degree. He had no doubt that we should secure all the milk we required, in one form or another, not only for the national milk scheme but for children, adolescents, and invalids during the coming winter.

LORD DAWSON said it might be worth considering whether, by propaganda or otherwise, something could be done to stop the slaughter at any rate of heifers. He agreed with Lord Woolton that the nation was well in health, but pointed out that it was the business of statesmen to watch for indications of changes in the tide. He did not want disease to come suddenly on us in a winter when, in all human probability, the nation would be rather more tired, more weary, suffering a little more from monotony, and more easily discontented, than in the first winter of the war. An independent inquiry should be set up to see whether or not there was a threat of diminishing milk production, and to decide how we should meet any such reduction.

Health Insurance Bill

Higher Income Limit and Benefit Rates

In the House of Commons on July 15, Mr. JOHNSTON moved the second reading of the National Health Insurance Contributory Pensions and Workmen's Compensation Bill. He said that the Bill was an interim measure to deal with immediate necessities, and it would not prejudice any conclusion which Parliament might reach after the war in regard to the future of social insurance. The Bill proposed an increase of 3s. in the weekly rates of sickness and disablement benefits. This was the first increase in these benefits for over twenty years, and the first time that women had been given the same increase as men. The limit of insurability for non-manual workers was raised from £250 to £420. Non-manual workers earning between £350 and £420 were also brought within the scope of the Workmen's Compensation Act. These changes would operate from next January 1.

In the debate which followed Dr. SUMMERSKILL said that the Bill was a miserable hotch-potch and did not give women equal treatment with men. The out-patient departments of hospitals, she said, were full of women who had had no proper provision made for their health. Dr. MORGAN complained that a vested interest had been allowed to creep into national health insurance. The investigation of alleged over-prescribing by panel doctors was also bad, and sometimes medical men were tried by their own rivals. Men who were the backbone of the medical services, and were trying to do their best for their patients while working under great handicaps, should be given more consideration.

Mr. ERNEST BROWN explained that no addition had been made to the maternity benefit because the Government, in deciding what they could do with the money available, came to the conclusion that they ought to put it to disablement benefit. They were confirmed in that by the nature of the disability and by the fact that there had been a tremendous development of the maternity and child welfare service quite apart from health insurance. The last increase in maternity benefit took place in 1920, but expenditure on maternity and child welfare had increased from £1,000,000 to £3,500,000 a year. About 70% of children under 1 year were taken to welfare clinics, and 50% of women attended ante-natal clinics. Speaking of the Bill generally, Mr. Brown said that there was much more than a cash side to it. There was a medical side.

One of the things that the committee which Mr. Greenwood had set up to review the whole question would have to apply its mind to would be how doctors, the public, and the State could get the best, from the point of view of preventive medicine, out of the various provisions already existing or from those which might be made in the future.

The Bill was read a second time and the financial resolution on which it is founded agreed to in committee.

Pension Appeal Tribunals

In the House of Commons on July 18, Sir IAN FRASER raised the question of the establishment now of appeal tribunals. He knew of cases of men who had come out of the Services disabled or sick, or who had died, but they or their widows had been granted no pension. He believed the Minister of Pensions and his medical staff judged these cases as fairly as they could, and that the Minister himself did his best to sort out the evidence, but it was hardly credible that the Department could be wholly without bias. It was essential that working-class people should have what appeared to them to be an absolutely fair chance of stating their case, and they could not have this so long as they had to go to the Ministry. Some kind of independent appeal tribunals were needed, like those which were set up in 1919 and which had functioned until the beginning of the present war. They were nothing to do with the Ministry of Pensions, but were impartial tribunals under the Lord Chancellor, and consisted of an ex-Service man, a lawyer of more than seven years' standing, and a doctor. From 1919 to the beginning of the war 53,000 pension cases were allowed and 113,000 turned down, so that practically 1 in 3 of the appeals was successful. There would be a few hundred or few thousand appeals to be heard at the present time, and on the evidence one-third would be deserving of a pension. He could not believe there were not sufficient lawyers to do the work, and while he knew doctors were very difficult to get, the Minister must find them for this work. Six, or at most a dozen, tribunals would meet the demand. It would be much more difficult to start dealing, say, in a year's time with ten times the present number of cases. People would feel they were having a fairer deal if their cases were heard now.

Mr. R. J. TAYLOR, Sir SMEDLEY CROOKE, Mr. A. BEVAN, and Mr. MANDER supported the motion; also Sir ROGER KEYES, who said that naval pensioners who were called up in wartime had suddenly to lead hard and strenuous lives. A great many died as a result, but when the cases came up before the medical tribunals it was said they died a natural death, not attributable to service. Arrangements were needed for an appeal in such cases. Mr. BEVAN thought that the Minister of Pensions did not call on the advice of independent medical men as a natural course. He only did so if the applicant or his relatives made efforts to this end. The Ministry's own medical advisers, who did nothing else but this sort of work, were apt to be guided by case decisions and to pile up generalizations.

Sir WALTER WOMERSLEY, Minister of Pensions, in reply, stated that he had already succeeded in getting cases like those mentioned by Sir Roger Keyes dealt with on a special basis. To Sir Ian Fraser he pointed out that the Government in June, 1940, had agreed that some right of appeal to an independent body would be essential after the war. He himself was wholly in favour of appeal tribunals. For the last war they were not set up until 1919 for the same reason as applied to-day—namely, that medical men with sufficient experience were not available. His inquiries had shown that at least twenty-six doctors and 200 lay staff would be required for the tribunals, with a further twenty-five doctors and 200 lay staff to prepare cases, and the appellants would also employ doctors. The shortage of doctors was being considered at the present time, and if it was possible to find all necessary personnel they could go ahead with setting up tribunals. The Minister had an independent medical referee nominated by the two Royal Colleges. Over 90% of the cases which would go to an appeal tribunal would do so on medical grounds, and they were sending many of these to an independent medical referee. Some people, however, did not feel satisfied unless they were examined. He would suggest to the bodies appointing referees that in such cases the claimant should be seen by the doctors themselves, but he could not order that this should be done.

Alien Doctors: Registration Procedure

On July 8 Mr. GROVES asked the Minister of Health why the Central Medical War Committee refused to grant interviews to foreign and overseas doctors affected by the Medical Registration Order, 1941; whether he was aware that in the case of aliens three forms and in the case of non-aliens two forms were required to be submitted; and whether he would recommend curtailment of this procedure. Mr. BROWN replied that the committee's staff could not interview these doctors, who numbered over 1,300, without seriously impeding their work of facilitating the employment and registration of the doctors. In any case no useful purpose would be served by interviews, because the committee had full written particulars of the doctors, which enabled them to submit names to the employing authorities, by whom the selections for interview were made. The answer to the second part of the question was "Yes," and to the third part "No."

Senile and Chronic Sick

On July 8 Sir ERNEST GRAHAM-LITTLE asked the Minister of Health whether he would distinguish between the categories of senile and chronic, or bedridden, sick; whether he was aware that at a hospital, of which he had been informed, there were, in October last, 500 patients, 95% of whom were bedridden; that the medical staff was only two in number; that, while there was a considerable number of assistant nurses, there were only ten with full training; that, notwithstanding intensive bombing near by, no effort was made to remove patients; and that early in October the hospital suffered a hit from a high explosive, as a result of which eighty-five patients and three nurses lost their lives. Mr. BROWN said he assumed that the first part of the question referred to his reply to a previous question on June 17 (*Journal*, June 21, p. 950). He could not give precise figures, but it might be taken that of the 4,000 described as removed from public assistance hospitals the great majority were bedridden, while of the 4,000 described as removed from shelters the great majority were not.

Venereal Diseases in Jamaica

Replying to Dr. Morgan on July 9, Mr. GEORGE HALL said there were three clinics for the treatment of venereal diseases in Jamaica, situated at Kingston, Montego Bay, and Port Antonio. Four full-time and two part-time medical officers were attached to the Kingston clinic and one part-time medical officer to each of the other two. It was impossible to estimate the proportion of those infected who sought treatment at the clinics. It was known, however, that an exceedingly small proportion of cases sought competent medical treatment in the early stage. The numbers of new cases admitted to the clinics in 1940 were:

		Male	Female
Kingston:			
Gonorrhoea	2,691	4,051
Syphilis	1,624	2,190
Montego Bay:			
Gonorrhoea	1,056	1,104
Syphilis	504	448
Port Antonio:			
Gonorrhoea	800	506
Syphilis	758	489

A temporary clinic at Kingston public hospital was equipped but is not in operation owing to lack of staff. Clinics were also planned for Spanish Town, St. Anne's Bay, Falmouth, Savanna-La-Mar, Black River, and Mandeville.

In the venereal diseases clinic at Kingston there were different departments for males and females, but, owing to lack of space and staff, not separate departments for children. There were no special facilities in the hospitals for treating children suffering from these diseases. The great majority of infected children were treated at the clinic as out-patients. Lord Moyne did not regard the position as satisfactory and was taking up the whole matter with the Governor of Jamaica. Provision of adequate treatment of children suffering from these diseases in the West Indian Islands was under investigation.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended June 28.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash—denotes no cases; a blank space denotes disease not notifiable or no return available.

† Owing to evacuation schemes and other movements of population, the birth and death rates have to be omitted for Northern Ireland.

EPIDEMIOLOGICAL NOTES

Infectious Diseases for the Week

Diphtheria and whooping-cough are the sole principal notifiable diseases to increase in England and Wales during the week. The latter is prevalent in the large towns, the figures for the current week (previous week in parentheses) being as follows: London 215 (160), Birmingham 106 (72), Liverpool 83 (89), Manchester 146 (148). In Scotland diphtheria has fallen, and also whooping-cough, but the former is still prevalent in proportion to the total population. In a recent circular the Department of Health lays stress upon the high susceptibility and mortality among children of 1 to 4 years, and local authorities are urged to intensify their immunization campaigns during the summer months while schools are closed, especially among children of pre-school age, in order to safeguard them from attack during the winter period, when the disease is more rife and more lethal.

Cerebrospinal Fever

Despite the high incidence of cerebrospinal fever in the first few weeks of the year, it was early suggested with some measure of confidence that an epidemic on the scale of that experienced in 1940 was improbable. This expectation has been fulfilled, as the accompanying chart reveals: the total numbers notified

during the first twenty-six weeks were 7,847 in 1941, compared with 9,229 in 1940. Although incidence was low at the beginning of the latter year, the rate of increase was higher than in 1941, attaining a high velocity at the end of January and contrasting strongly with the more leisurely rise this year. In the present year the acme was reached a week earlier, but the decline, like the rise, has been leisurely, although characterized, as in 1940, by occasional exacerbations due to local outbreaks. The infection has been milder on the whole this year, and low case-fatality figures are expected when the records are collected. Although several small series with case mortalities as low as 5% are not uncommon, the general rate for the whole country has so far remained in the region of 15%. More intensive chemotherapy will doubtless help to reduce this figure substantially.

The Minister of Health has made the following acting appointments: Mr. J. C. Wrigley, C.B., to be Deputy Secretary of the Ministry of Health in the place of Mr. A. N. Rucker, C.B., C.B.E., who has been seconded for special duties. Mr. E. G. Bearn, C.B.E., to be an under-secretary in general charge of the preparatory and operational activities of the Ministry arising out of the war, other than those associated with the Emergency Medical Service. Mr. T. Lindsay to be a principal assistant secretary. Mr. P. N. R. Butcher to be an assistant secretary. Mr. Howell E. James to be chief general inspector in the place of Mr. C. F. Roundell, C.B.E., retired.

Medical News

Lord Horder has been appointed personal adviser to the Minister of Food, Lord Woolton, on medical aspects of food problems.

The annual general meeting of the Medical Society for the Study of Venereal Diseases will be held at 11, Chandos Street, W., on Saturday, July 26, at 2.15 p.m. At 3 p.m. there will be a discussion on "The Present Trend of Incidence of Venereal Diseases in England and Wales and the Methods of Control," to be opened by Colonel L. W. Harrison, followed by Dr. Margaret Rorke, Lieut.-Colonel T. E. Osmond, Dr. Letitia Fairfield, Surgeon Commander D. Duncan, Surgeon Lieut. Genevieve Newcastle, and Wing-Commander J. M. Kilpatrick.

The National Council for Mental Hygiene has arranged a public meeting to be held at Manson House, Portland Place, W.1, on Thursday, July 31, at 5 p.m., when Mr. Kenneth Walker, F.R.C.S., will deliver an address on "The Need for a Positive Philosophy of Life," with Dr. H. Crichton-Miller in the chair.

With its issue of July 5 the *Pharmaceutical Journal* founded by Jacob Bell enters on the second century of its existence.

The Gunning Victoria Jubilee Prize, for the period 1936 to 1940, was presented at a meeting of the Royal Society of Edinburgh on July 7 to Sir James C. Irvine, D.Sc., F.R.S., Principal and Vice-Chancellor of the University of St. Andrews, for his distinguished contributions to organic chemistry. In making the presentation Prof. E. T. Whittaker, the President, said that the value of the contributions by Sir James Irvine had been recognized by the Royal Society of London, which had honoured him with the Davy Medal, and by the Chemical Society, which awarded him the Longstaff Medal in 1933.

The names of Dr. William Fraser Annand, consulting physician, and Dr. Harry Winter, resident surgical officer, Coventry and Warwickshire Hospital, and Dr. Noel Rowland Hutchinson Holmes, medical officer, Coventry A.R.P. Casualty Service, have been brought to notice for brave conduct in civil defence.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS of their articles must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be addressed to the Secretary.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent*, London; SECRETARY, *Medisecra Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Income Tax

Fall in Practice Income

"DELTA" was called up in September, 1939, for the E.M.S., and has been assessed for the year to April 5, 1940, on (a) the basis of his practice profits for 1938-9 plus (b) his salary under the E.M.S. for the period September 2, 1939, to April 5, 1940. Is this correct?

* * Yes, but if "Delta's" aggregate earned income for 1939-40 is not more than four-fifths of his earned income as assessed for that year he is entitled to have the practice profits calculated on the basis of the actual year (Finance Act (No. 2) 1939, Section 11). Whether relief is obtainable in that way will of course depend on the amounts concerned.

LETTERS, NOTES, ETC.

Abdominal Symptoms after Opium

Mr. P. L. BLAKELY (Shanklin) writes: May I, as a pharmacist, ask if it is quite fair for Dr. Jas. Scott (June 21, p. 952) to suggest that all the blame for certain abdominal symptoms, which he describes, lies upon the shoulders of opium? Pulv. Dover, alias pulv. ipecac. co., is a partnership. One does not need to refer much to Prof. A. J. Clark's *Applied Pharmacology* to know that the crimes seem much more like those of ipecacuanha. We can probably acquit the potass. sulph. There is 10% of ipecacuanha in pulv. ipecac. co. as there is of opium. Ipecacuanha contains the irritant alkaloids of emetine and cephaeline. The 1/4-grain dose of morphine mentioned at the end of Dr. Scott's letter is equal to the morphine content of 2½ grains of opium or 25 grains of Dover's powder. Perhaps it would be presumptuous of me to point out that the actions of opium are not necessarily the same as those of 1/10 part of its weight of morphine owing to the presence in opium of several other alkaloids.

St. Columba's Hospital for Advanced Cases

Mr. NORMAN A. SPROTT, F.R.C.S., writes: Many of your readers may be glad to know of the services provided by this hospital. In peacetime most of the patients came from a few large general hospitals, eager to fill our beds as soon as they were available, and there was no reason to make the institution known to a wider public; but wartime conditions have lessened the demand on our beds from the usual sources, with the result that our waiting lists have sometimes been reduced to vanishing-point, and there have even been empty beds, particularly in the men's wards. I cannot help feeling that these beds could be filled many times over if more members of the profession were aware of their existence. St. Columba's Hospital (Swiss Cottage, London, N.W.3) was founded to serve the needs of incurable patients, many of them dying of malignant disease, during the last few months of their illness. It provides care rather than cure for those beyond the reach of operative or radiological treatment. Infectious and mental cases are not admitted. Patients are expected to contribute, according to their means, from two to five guineas a week, for which they receive medical and nursing attendance, drugs, and dressings. There are no extras. The hospital provides for a class of patients that cannot easily be nursed at home or yet afford to remain for long in a private nursing home, and for whom there is otherwise usually no alternative but a council hospital. St. Columba's stands in a large garden in South Hampstead, readily accessible from the West End of London, with an excellent bus and underground service. Considering the desperate nature of the cases admitted it is a remarkably happy place. Many medical practitioners and others visiting the hospital have been impressed by its peaceful, friendly atmosphere. There are no private rooms at St. Columba's, and it seems to me that these patients, once they appreciate the fact that cure is out of the question, are generally happier in a ward with others similarly afflicted than they would be in a private room at a nursing home or living at home with their relations. The hospital is interdenominational, and the spiritual needs of the patients are well cared for.

Recruitment for Nursing

Efforts to bridge the gap between the time girls leave school to when they are old enough to enter hospitals are referred to in a report issued by the Nursing Recruitment Centre. Although the Centre, financed by the King Edward's Hospital Fund for London, has only been in existence just over a year, some 450 applications have been received from girls of 15 or 16 who would not normally be ready for hospital training for at least two years. The report states: "If the nursing register goes on growing at this rate of 5 or 6 a day, it will total over 1,000 names by the end of the year, and more than double that number by the end of next year." The Centre sends these candidates leaflets on nursing, lists of pre-nursing courses, and individual advice about the best means of bridging the gap. It aims at keeping in touch with them until they are old enough to apply for hospital training.

Disclaimer

Mr. A. H. McINDOE writes: I wish to make it clear that I was in no way responsible for the undesirable comments recently made in the Press in regard to myself and the Maxillo-facial Unit at East Grinstead. I have no knowledge of the writer, have given no interviews, and wish to dissociate myself completely from publicity of this type.

Corrigendum

We regret that the price of the seventh edition of *Methods of Treatment*, by Prof. Logan Clendening and Dr. E. H. Hashinger, was incorrectly given last week (p. 89) as 25s. net; this should have been 50s. net.

THE TOXICITY OF SULPHONAMIDE DRUGS TO CELLS IN VITRO*

BY

Department of Physiology, University of Cambridge

(WITH SPECIAL PLATE)

The administration of sulphonamide drugs by injection or by mouth for the prevention and treatment of wound infection is in many cases giving place to a more direct method, in which the powdered drugs are applied locally to the wound surfaces (Jensen, Johnsrud, and Nelson, 1939; Legroux, 1940; Colebrook, 1940; Hawking and Piercy, 1941; Colebrook and Francis, 1941; and others). The first method yields concentrations in the blood and tissue fluids usually ranging from 1:10,000 to 1:100,000, while the second establishes local concentrations ranging from saturation strength downwards. This second method raises problems concerning the toxicity of sulphonamide drugs to living cells which could hardly be expected to arise in acute form after other methods of treatment. Tissue culture provides one method of studying problems of this sort, because it is capable to some extent of reproducing *in vitro* the influence of the drugs on the behaviour of the various types of cells which play a part in wound healing. By means of it one should be able not only to rank a series of drugs in the order of their toxicity to living cells, but also to obtain a clear idea of the order of magnitude of the concentrations which are lethal to them.

The drugs chosen for investigation were sulphanilamide, sulphathiazole, sulphapyridine, and (in some tests) sulphadiazine; and various aspects of their influence on the behaviour *in vitro* of cells of three main types—fibroblasts, macrophages, and epithelia—have been put on record. In each case it has been possible to draw an instructive comparison between the action of the sulphonamide drugs and that of proflavine.

The method of direct application has been kept constantly in mind. For instance, a comparison of the drugs at equal or chemically equivalent concentrations alone would be misleading, for their *effective* toxicity depends largely upon solubility, and on other factors—such as the rate of transport from a site of local application—which themselves largely depend upon solubility. The basic cultivation media—adult chicken plasma or serum, in some cases with the addition of chick embryonic extract—are those which have come to be regarded as standard in cultivation work. None of the sulphonamide drugs affects the coagulation of plasma, and none is notably surface-active: Except with the highest concentrations of sulphanilamide, where a slight but significant osmotic effect must be

exerted, the interpretation of experimental results is not therefore complicated by secondary reactions of the reagents employed. Sulphonamide drugs prove, however, to be considerably more soluble in serum than in Tyrode's solution (see table, p. 153).

I. Action of Sulphonamide Drugs on Fibroblasts of a Cultivated Strain

Willmer (1933) and Willmer and Jacoby (1936) have described a technique for recording mitotic activity and cell-movement rate in fibroblast colonies which has given consistent results for some years under a wide variety of conditions. In principle it consists in photographing directly on 3-inch bromide paper film a sample of cells (100 to 400) from the peripheral part of a colony of fibroblasts growing in Carrel flasks to which a photographic glass base has been fitted. The photographs are taken automatically at six-minute intervals through specially designed inverted microscopes. Estimates of the percentage of cells in the photographic field undergoing mitosis per hour are made by a later detailed analysis of the films.

In the experiments to be described in this section single cultures from a strain of fibroblasts from the frontal bone of a 12-day-old chick embryo were planted into 30-mm. Carrel flasks containing a *coagulated phase*—in which the cells grow—of 0.2 ml. of an equal mixture of plasma and 20% embryo juice in Tyrode's solution, and a *supernatant fluid* of 1 ml. 20% embryo juice in Tyrode. "100% embryo juice" is the undiluted fluid removed by centrifugation from 8-day-old chick embryos crushed in a Latapie press. After twenty-four hours' cultivation at 38° C. a sufficient number of cells wander into the medium to make photography possible. Normal growth is recorded for approximately four hours. The supernatant fluid is then replaced by 1 ml. of a solution of the appropriate drug in a medium otherwise identical. The response of the cells to the drug is recorded for fourteen to eighteen hours, after which the supernatant fluid is again replaced by 1 ml. of 20% embryo juice in Tyrode. In short, it is possible over a stretch of twenty-seven to thirty hours to record normal growth, the action of the drug, and the nature of the recovery of the cells, if any takes place, from the action of the drug.‡

In analysing the results the hourly fluctuation in mitotic rate is smoothed out by calculating the mean mitotic

* A report to the War Wounds Committee of the Medical Research Council.

† For the expenses of the research this author is indebted to the Research Committee of the University of Birmingham and to the Medical Research Council.

‡ For the maintenance of these cultures and other technical assistance, one of us (E. N. W.) is indebted to Mrs. Simon Reuss.

percentage over three-hour stretches, an adjustment which does not obscure major trends in the curve of growth. By this method the actions of sulphanilamide, sulphathiazole, and sulphapyridine have been tested at final concentrations in the culture flask corresponding to about 70% of that at which the drugs are saturated in Tyrode's solution at 38° C.* The results of these experiments, and others in which the drugs were applied at lower concentrations, are illustrated in Chart I (i, ii, iii). They may be summarized as follows:

Sulphanilamide at a final concentration of approximately 1:100 in the culture flask brings the division and migration of the cells to a standstill. Both are resumed within five hours after removal of the drug from a treatment lasting fourteen to eighteen hours (Chart I, iii, b). At a concentration of 1:1,000 sulphanilamide exerts no depressant action (Chart I, iii, a).

CHART I.—The action of sulphonamide drugs and proflavine on fibroblasts of a cultivated strain: the percentage of cells undergoing mitosis per hour, averaged over 3-hour periods (vertical axis), as a function of the time of incubation (horizontal axis). The vertical lines enclose the stretch over which the drugs were applied in solution in 20% embryo juice in Tyrode. The final concentration in the culture flasks corresponds to about 70% of the figures quoted. (i) a, b, Sulphapyridine 1:1,000. (ii) a, Sulphathiazole 1:10,000; b, 1:1,000; c, 7:700 approx. (iii) a, Sulphanilamide 1:1,000; b, more than 1:100. (iv) Proflavine 1:1,000,000.

Sulphathiazole differs from sulphanilamide in the wide range of concentration (1:10,000 upwards) over which it exerts an appreciable inhibitory effect; but even the 70% saturated solution fails to abolish mitosis completely (Chart I, ii, a, b, c). Recovery from fourteen to eighteen hours' subjection is rapid and complete, and shows a marked tendency towards compensatory overgrowth.

Sulphapyridine fails to affect mitosis or migration in 70% saturated solution (Chart I, i, a, b).

The order of increasing effective toxicity is therefore simply that of increasing solubility, although sulphathiazole appears to be the least favourable for growth at any assigned concentration. Only sulphanilamide could be expected to exert a clinically significant inhibitory action, but particular attention should be paid to the fact that recovery from its action under the conditions described here is rapid and complete. In marked contrast to these results are those from proflavine (Chart I, iv), which exerts a total and irreversible inhibitory effect, accompanied by disintegration of cells, at concentrations lower than 1:1,000,000.

* The solutions referred to in this section as "saturated" were prepared by prolonged incubation of an excess of the crystals in Tyrode (pH 7.8) at 38° C., followed by immediate Seitz filtration. The concentrations were found to be: sulphapyridine, 1:1,000 approx.; sulphathiazole, 1:700 approx.; sulphanilamide, more than 1:100.

II. Action of Sulphonamide Drugs on Freshly Explanted Fibroblasts

The preceding section records the action of sulphonamide drugs on tissues which have been grown for upwards of four passages (8 to 12 days) *in vitro*. It can be shown that during the course of cultivation the power of tissue fragments to resist the action of inhibitory substances rises sharply to a figure which eventually becomes constant and which is characteristic only of a particular "strain" of cells. Tests of an alternative type to those described in Section I can be devised which take advantage of the fact that freshly explanted tissues of a given source and embryonic age possess a characteristic power of resistance to growth inhibition. These tests consist in determining the concentration of a drug which is sufficient and necessary to suppress all outgrowth from a standard explant for 24 hours at 37° C. The method has been described by Medawar (1937, 1940). The standard explant is a fragment of the wall of the ventricle of a 10-day-old chick embryo heart, and the standard medium consists of 0.1 ml. of an equal mixture of cockerel plasma and a solution of the drug in Ringer's solution. Falling dilutions of the drug are prepared, at each level of which five or ten explants are incubated in separate cultivation chambers. After twenty-four hours it is easy to determine by inspection the concentration which is just high enough to inhibit all outgrowth. In the neighbourhood of this "threshold point" concentrations of the drug differing from each other by less than 10% are distinguishable.

After 48 hours' subjection to the action of the drug a further test can conveniently be applied. This consists in reculturing each explant, after washing for one hour in Ringer at room temperature, into a plasma and embryo-extract medium. A later inspection of these subcultures then provides one type of estimate of the minimum lethal concentration of the reagent used, since it is possible to record what concentration of the drug, under the conditions described, the cultures can withstand for forty-eight hours without being "killed"—i.e., without undergoing changes irreversible by further cultivation in a normal medium. If the drug is comparatively non-toxic the cells are not killed by a concentration higher than that necessary to inhibit growth totally; a more toxic substance (e.g., proflavine) will, however, kill the cells at a concentration lower than that which allows a certain amount of growth to take place within the first twenty-four hours after explantation.

Results of test of these two types on four sulphonamide drugs may be summarized as follows:

Sulphanilamide.—The threshold point corresponds to just above half the concentration at which the drug is saturated in Ringer at 37° C. (1:150 approx.). Isolated cells which migrate from the explant at this concentration are smaller than normal and highly refringent. Recovery from forty-eight hours' subjection to this concentration is rapid and complete, but fresh explants are not able to withstand twenty-four hours' exposure at 37° C. to a saturated solution of the drug in the culture medium (1:60 approx.†). Osmotic effects as such probably play very little part in these reactions. Heart fibroblasts are capable of withstanding much higher osmotic pressures (e.g., that generated by 5% maltose) for much longer periods.

Sulphathiazole.—The threshold concentration proves to be approximately that at which the drug is saturated in the culture medium at 37° C. in the presence of excess crystals (1:500†). Recovery from forty-eight hours' subjection is rapid and complete. At concentrations as low as one-third of saturation strength cells which migrate into the culture medium during the

† These figures for solubility in 50% plasma are approximations based on the table of solubility in 40% serum which appears later (p. 152).

first day show no further progress between the twenty-fourth and the forty-eighth hour of cultivation.

Sulphapyridine (Plate, Fig. 7) and sulphadiazine permit the free migration of fibroblast cells among crystals lying in saturated solution in the culture medium at 37° C., and no reading can therefore be obtained by the method of thresholds. Cells at this concentration show minor abnormalities of a non-specific type—e.g., a tendency towards vacuolization—but are not abnormally refringent. Growth proceeds normally on recultivation. Sulphadiazine is slightly but not in a practical sense significantly more toxic than sulphapyridine.

These results on freshly explanted fibroblasts reinforce those of the previous section. They further suggest that neither sulphapyridine nor sulphadiazine when applied to wound surfaces need be expected to exert any depressant action on regenerative growth.

Proflavine in neutral solution in Ringer reaches threshold strength at a concentration of 1:120,000 ($\pm 5\%$), but recovery from forty-eight hours' subjection is only possible from an ill-defined concentration in the neighbourhood of 1:250,000. While they indicate that proflavine is a highly toxic substance, these figures are notably lower than those quoted in Sections I and III. The reason for this is probably that proflavine is powerfully adsorbed upon tissues—as it is, for instance, upon glass; so that the dose administered is as important as the concentration. The dose applied in the experiments described in Sections I and III is 1 γ , while the dose corresponding to the figure for minimum lethal concentration for forty-eight hours' treatment (1:250,000) is only 0.4 γ .

Rate of heart-beat in isolated fragments is profoundly stimulated by proflavine. The threshold for heart-beat inhibition and growth or cell-movement inhibition are strikingly different, for 10-day chick-heart explants are just capable of beating for forty-eight hours in a 1:10,000 solution of proflavine—i.e., in a concentration ten times greater than that representing threshold level for growth inhibition.

III. Action on Macrophages

A study of the action of sulphonamide drugs on macrophages is of particular value in a number of ways. The macrophages are themselves intimately concerned in the process of wound healing. The cells to be studied are taken from an adult organism. In culture, embryo extract and a plasma coagulum can be dispensed with: macrophages thrive and multiply actively in dilute serum. Conditions are thus more closely akin to those *in vivo* than is generally the case with tissue culture. Here as elsewhere, however, the conditions under which the cells are tested *in vitro* are more severe than they are in clinical application.

Pure cultures of macrophages prepared by Baker's (1933) technique from adult hen blood form a unicellular layer of isolated individuals clinging to the bottom of the ordinary D-type Carrel flask. These blood macrophages or "monocytes" are morphologically and functionally indistinguishable *in vitro* from the so-called tissue macrophages (Carrel and Ebeling, 1926; Jacoby, 1938). Attached to the flask they can be kept alive and multiplying for months under repeated feeding with 1 ml. of 20 to 40% blood serum in Tyrode per flask. Cultures were used for experiments after not more than eight days' cultivation in this basic medium.

In some preliminary experiments the cells were treated for seven days with somewhat dilute solutions of the appropriate drug mixed with serum. The range of concentrations used was: sulphanilamide 1:1,500 \rightarrow 1:5,600, sulphathiazole 1:1,600 \rightarrow 1:5,600, sulphapyridine 1:2,700 \rightarrow 1:9,200. The experimental medium was replaced once, on the third of the seven days of treatment. Under these con-

ditions the macrophages remained outstandingly healthy, showing a range of variation in morphological appearance not distinguishable from that of control cultures.

Detailed quantitative records of mitotic activity, accompanied by morphological studies, were then made by serial photography according to the technique described in Section I. In normal cultures (Jacoby, 1937a) feeding with serum in Tyrode brings about, after a latent period lasting from twenty to twenty-four hours, a major wave of mitotic activity reaching a peak between the thirtieth and the fortieth hour. Less regularly, the major wave is followed by a minor wave with a peak between the fiftieth and the sixtieth hour, after which the cells gradually return to quiescence. The whole period represents a single growth cycle, the end of which is taken as zero time. At zero time the drugs dissolved in 40% serum were applied and left in contact

CHART II.—The action of sulphonamide drugs on adult hen-blood macrophages: the percentage of cells undergoing mitosis per hour, averaged over 2-hour periods (vertical axis), as a function of the time of incubation (horizontal axis). Except in iii b, where the arrow indicates the time at which the drug solution was replaced by normal feeding fluid, the drugs dissolved in 40% serum were in contact with the cultures throughout the period recorded. The normal latent period of about 20 hours is not included in the graphs.

- (i) a. Sulphapyridine 1:3,400; b. sat. sol. (1:800 approx.).
(ii) a. Sulphathiazole 1:2,300; b. average curve of 1:1,000 and sat. sol. (1:500 approx.).
(iii) a. Sulphanilamide 1:2,300; b. 1:500.

with the cells for a whole growth cycle—except where strong inhibition was obvious, in which case the experimental fluid was replaced by fresh dilute serum after forty-eight hours or sooner (Chart II, iii, b). Serial photography was started towards the end of the normal latent period and carried on for the next forty to fifty hours so as to cover the main phase of the growth cycle. The percentage mitoses per hour were determined and plotted as the average of two-hour periods.

At the lower range of concentrations referred to above, analysis by this method (Chart II, i, ii, iii, a) did not reveal any depressant effect on mitosis; and phagocytosis of disintegrating by normal cells—a process already known from normal cultures (Jacoby, 1937b)—was repeatedly observed. These a curves can thus be conveniently used to illustrate normal growth under serum feeding.

It was then found that the drugs were considerably more soluble in serum than in Tyrode (see table), and

use was made of this fact by *directly* dissolving weighed quantities of the drugs in 40% serum at 39° C. for twenty-four hours. Concentrations were thus reached which

should be similar to those in wounds to which the powdered drugs are applied. At this higher range of concentrations (Chart II, i, ii, iii, b) certain interesting distinctions appeared, which may be summarized as follows:

Sulphapyridine.—The saturated solution in 40% serum (1:800 approx.) had almost no inhibitory effect within the growth cycle recorded (Chart II, i, b). The cells remain normal in appearance and in phagocytic activity; they move and divide in the neighbourhood of crystals.

Sulphathiazole.—At 1:1,000 or 1:500 (saturated solution) in 40% serum (Chart II, ii, b) the size of the major mitotic wave is somewhat reduced, although mitosis still remains vigorous. Certain morphological changes, however, persist during the entire period of application, and indicate a toxic effect of the drug: the cells round off as spheres or disks and become filled with a fair number of fat granules, while amoeboid movement is largely suppressed (Plate, Fig. 1). Within one or two days of replacing the experimental medium with fresh serum, normal morphology and growth are restored (Fig. 2).

Sulphanilamide saturated in 40% serum (1:60 approx.) and also at 1:100 causes disintegration and death of the cells. From a twenty-four-hours' application there was no recovery on feeding with fresh serum. These results do not exactly agree with those from fibroblasts reported in Section I; but differences in cultural conditions, in the size and distribution of the cell popula-

replacing the drug medium with fresh serum, normal growth is restored (Chart II, iii, b). In 1:1,000 similar gross inhibition was sometimes seen, while in other instances there was merely a prolongation of the normal latent period of twenty to twenty-four hours to thirty-six hours or more. This was followed by a marked mitotic response, during the course of which the morphological appearance of the cells, initially similar to that in higher concentrations of sulphathiazole, underwent a *spontaneous recovery* while still under the influence of the drug. Only a certain accumulation of fat granules persisted in the cells (Fig. 3). Again, recovery was quick and complete on feeding with fresh serum (Fig. 5). Phagocytosis was not observed in sulphanilamide cultures at a concentration of 1:500 or higher.

These results indicate that the relative toxicity of the three sulphonamides is the same for macrophages as for fibroblasts. A fact of particular interest is that while at equal concentrations sulphanilamide inhibits the division of macrophages much more strongly than sulphathiazole, the

latter produces more pronounced and persistent morphological changes indicative of impaired cellular vitality. In so far as the comparatively small number of these lengthy experiments makes possible, the results are summarized in Chart III, in which the amount of growth between the twenty-third and forty-eighth hours, expressed as the sum of the hourly percentages of mitosis, is plotted against the concentration of the drugs.

Proflavine was also tested on these macrophages. In a final concentration as low as 1:1,000,000 in 30% serum applied for twenty hours it caused complete disintegration of the cultures.

IV. Action on Epithelia

The growth of epithelia *in vitro*, while it may be prolonged and abundant, is much less regular and predictable than that of mesenchyme cells, and no satisfactory method for the quantitative analysis of their growth has yet been devised. The surface of the plasma coagulum is used, following the prescription of Ebeling (1924), and in the case of fibrinolytic epithelia it is desirable to wet the surface of the hardened coagulum with a saline solution of the drug at the appropriate concentration. This is done by applying the solution with a pipette over the whole surface of the clot and then removing it so far as is possible. The test tissues used were 10-day chick-embryo intestine and lung and late rat-embryo kidney. The results for the four drugs considered in Section II may be summarized as follows. Inhibition to fibroblasts and epithelia from a common source proceeds *pari passu*, and there is no indication of differential toxicity favouring one type or the other. Either epithelial sheets and fibroblasts grow together or neither grow. The concentrations at which lung and intestinal epithelia from the 10-day-old chick are just able to grow for twenty-four to forty-eight hours *in vitro* are not closely defined, but they may be reasonably approximated to the figures already quoted as threshold concentrations for the inhibition of 10-day chick-heart fibroblasts (1:150 and 1:500 approx. for sulphanilamide and sulphathiazole

LEGENDS FOR THE SPECIAL PLATE

respectively). Epithelial sheets which occasionally spread in higher concentrations of sulphanilamide rapidly undergo maceration into separate cells.

A striking feature of these experiments is the ease with which epithelial sheets grow among and invest crystals of sulphapyridine and sulphadiazine lying in saturated solution in the culture medium. Needles of recrystallized sulphadiazine, for instance, act as a support for the growing cells; they tend to become completely invested by an epithelial sheet, forming a tent for which the crystal acts as tent-pole (Fig. 6). In short, it is in the highest degree unlikely that under the less stringent conditions of application *in vivo* either of these drugs could retard the new growth of epithelia over a raw surface.

Proflavine likewise shows no power of differential inhibition. The concentration which just permits the spread of epithelia from the intestine of the 10-day-old chick lies between 1:100,000 and 1:120,000.

Discussion

At the present time no method of analysing the general toxicity of drugs to living cells has been devised which combines the accurately controlled and detailed observations of tissue culture with conditions directly comparable to those under which the drugs are applied clinically. Owing to the absence of a circulatory system and of the detoxicating mechanisms of the organism as a whole, tissue culture tests are more stringent than clinical ones—a fact partly counterbalanced by the greater resistance of embryonic tissues to inhibition of their growth. This reservation can hardly apply, however, to the experiments on "adult" cells described in Section III.

The experiments described above, independently performed on a variety of cell types, are consistent among themselves in the sense that they rank the drugs considered in the same order of effective toxicity, while the order of magnitude of the significantly inhibitory concentration is found to be the same throughout. The results are in accord with somewhat less detailed observations by Wolff and Julius (1939) on sulphanilamide. Comparison of the drugs at equal concentrations shows sulphathiazole to be the least favourable, in view of the wide range of concentration over which it is appreciably inhibitory and of its pronounced effect on the morphological appearance of macrophages; but the effective toxicity—under the conditions of direct application which were envisaged in these experiments—is determined by relative solubility, and falls into the decreasing order: sulphanilamide→sulphathiazole→sulphapyridine and sulphadiazine. Studies on red or white blood cells by Fleming (1938), Osgood (1938), and Bullowa *et al.* (1940) tend towards the view that sulphanilamide is feebly toxic in high concentrations, while sulphapyridine is completely non-toxic. The action of various drugs on brain tissue has been recorded by Russell and Falconer (1940a, 1940b): powdered sulphanilamide and sulphapyridine produce no specific reaction, while 0.1% proflavine at pH 6.2 is hardly more harmful than neutral saline. The second of these observations contrasts sharply with the toxicity of proflavine as determined by tissue culture tests. Proflavine appears in these as a highly toxic substance, the order of magnitude of the significantly inhibitory concentration being 10^{-5} or 10^{-6} .

The experiments described above give one no ground for believing that the sulphonamide drugs accelerate growth, though such an action might be brought about indirectly by suppressing the inhibitory action of infective organisms (Levaditi *et al.*, 1940). They do not exclude the possibility that sulphanilamide and sulphathiazole in particular may exert an inhibitory effect on wound healing, however

transient (as Bricker and Graham, 1939; Jeffrey, 1940; Veal and Klepser, 1941, have found for sulphanilamide). Colebrook and Francis (1941) do not, however, find that sulphanilamide exerts an appreciable inhibitory effect when dusted on to superficial wounds, and Taffel and Harvey (1940) have not been able to confirm the observations of Bricker and Graham. The most striking feature of the tissue-culture studies described above is the remarkably feeble inhibitory action upon tissue cells of all the sulphonamide drugs considered. There is a *profoundly significant difference* between the thresholds for bacterial and cellular inhibition in all three cases. In short, the evidence from tissue cultivation is that in choosing between one sulphonamide drug and another for direct application to wounds their relative effects on tissues can be disregarded in favour of their relative specific bactericidal powers.

Summary

The treatment of infected wounds by direct chemotherapy with sulphonamide powders justifies a detailed analysis of the action of these drugs on living cells.

The effects of sulphanilamide, sulphathiazole, sulphapyridine, and (in some tests) sulphadiazine on fibroblasts, macrophages, and epithelia have accordingly been tested by a number of different cultivation techniques.

The drugs were applied in concentrations ranging from saturation strength downwards, and for periods lying between fourteen hours and three days.

Compared at equal concentrations, sulphathiazole is the most toxic of these drugs.

The effective toxicity under the conditions of clinical application is, however, determined by the relative solubility of the drugs, and falls into the decreasing order: sulphanilamide→sulphathiazole→sulphapyridine and sulphadiazine.

The growth inhibition and unfavourable morphological effects produced by the highest concentrations of sulphathiazole are followed by complete recovery on removal of the drug. Cells are not capable of withstanding prolonged subjection to the highest concentrations of sulphanilamide, but recovery readily takes place from concentrations of 1:150 downwards. Neither sulphapyridine nor sulphadiazine inhibits significantly in saturated solution at body temperature.

The feeble inhibitory action of the sulphonamide drugs is favourably contrasted with that of proflavine.

Attention is called to the profound difference between bacteriologically effective concentrations and those which are appreciably toxic to cells.

It is therefore suggested that in the choice of sulphonamide powders for direct application to wounds their relative specific bactericidal power should outweigh other considerations.

We wish to thank Colonel L. Colebrook, Dr. F. H. K. Green, and Dr. F. Hawking for their helpful advice and criticisms.

ORIGIN, DIAGNOSIS, AND MANAGEMENT OF EARLY BRONCHOGENIC TUBERCULOSIS

BY

G. GREGORY KAYNE, M.D., M.R.C.P., D.P.H.

*Tuberculosis Medical Officer, Middlesex County Council**

(WITH SPECIAL PLATE)

There is scarcely a report by a medical officer of health, tuberculosis officer, or sanatorium superintendent that does not refer to the advanced stage of the disease in which those suffering from pulmonary tuberculosis first come for treatment under the tuberculosis scheme. The cry is, "If only we could get the cases early!" The emphasis laid on this plea implies that if people were seen early in the development of the disease transmission of infection to others would be avoided and the disease would be made to heal in all patients. It is not surprising, therefore, that some advocates of mass radiological examinations see in them the key to the control of tuberculosis. This should not, however, be taken for granted, because up to the present relatively few such early cases have been detected, treated, and followed up: indeed, no clear-cut conception of what constitutes an early case is being taught.

Definitions

The term "pulmonary tuberculosis" itself requires clarification. It usually refers to the disease commonly seen in adolescents and adults, characterized by gradual destruction of the lungs as a result of the intrabronchial spread of massive doses of bacilli following cavitation of a tuberculous focus. But other active tuberculous lesions are common in the human lung—those of the primary infection and of the dissemination that follows it. It would be well, therefore, to use the term "pulmonary tuberculosis" as implying any active lesion in the lung belonging to any phase in the evolution of tuberculosis, and to restrict the use of another term—that of "bronchogenic tuberculosis"—to the common type of bronchogenic disease.

In discussing the early stage of bronchogenic tuberculosis mention must be made of those lesions in the lung which occur during the phase of dissemination in the evolution of tuberculosis (Kayne, Pagel, and O'Shaughnessy, 1939) (of which chronic miliary tuberculosis is but one clinical type), for such haematogenous cases may simulate bronchogenic tuberculosis when the lesions cavitate (Case 1). These thin-walled "punched" cavities have, however, little caseous matter in their walls and probably only rarely lead to intrabronchial transmission of bacilli. The common

beginning of bronchogenic tuberculosis is a single focus, usually in the upper part of the lung, which enlarges, liquefies, and cavitates, when secondary foci develop as a result of intrabronchial transmission (this process has been accurately reproduced in animals). Since the disease takes on its grave aspect with liquefaction and cavitation of the first focus, early bronchogenic tuberculosis must be defined as the earliest recognizable caseous focus which has not yet opened into a bronchus. Such a focus does not give rise to abnormal physical signs, is often associated with no symptoms, either local or constitutional, and may even present no evidence of toxæmia as shown by a raised sedimentation rate or altered blood picture. But it can be detected in a radiograph of good quality when it is less than a quarter of an inch in diameter unless the focus is entirely hidden by the shadow of a bony structure. It may appear as a uniform cloudy haziness or as a group of nodules, some of which coalesce. To summarize, early bronchogenic tuberculosis is the smallest radiologically detectable focus with potentialities for liquefaction.

A small shadow in the upper part of the lung field may be caused by other tuberculous lesions (active or healed). Thus the pulmonary focus of an active primary infection may sometimes be seen as a distinct shadow in the lung field. Nowadays the primary infection occurs often during adolescence and not very rarely even in adults, but, as in children, enlargement of at least the corresponding hilar shadow is then seen—a change not met with in the early lesion of bronchogenic tuberculosis. Again, the pulmonary foci of dissemination associated with and following the primary infection may resolve completely, or may leave behind a few tiny nodules scattered throughout the lungs, or a group of rather bigger nodules at the apices (Simon foci), or one or more larger foci a quarter of an inch or more in diameter. The latter foci usually consist of a caseous centre with fibrotic capsule,

and have been termed "round foci." Finally, quite sizable lesions of bronchogenic tuberculosis may develop and heal unsuspected, so that one is presented with a single residual non-active focus which may be mistaken for a first or early focus of bronchogenic tuberculosis.

Origin of Bronchogenic Tuberculosis

The early lesion of bronchogenic tuberculosis occurs in an individual who has already overcome his primary infection, though the interval between the onset of the first infection and the lesion of bronchogenic tuberculosis may be as short as a few months (Case 2). There are several possible theories of the origin of the early lesion, since it is known that bacilli may remain alive in an apparently healed primary pulmonary focus (rarely), a primary glandular focus (more commonly), and in foci of dissemination (quite commonly). As a result of lowering of resistance or fol-

LEGENDS FOR THE SPECIAL PLATE

FIG. 1.—Case 1 (May 31, 1939). Coarse miliary mottling in upper half of each lung.

FIG. 2.—Case 1 (June 11, 1940). In addition there is now a thin-walled irregular cavity in right upper zone.

FIGS. 3 and 4.—Case 2. Showing progression towards bilateral cavernous bronchogenic tuberculosis (films taken in August, 1939, and November, 1940).

FIG. 5.—Case 3. Round focus with calcified shell in left infraclavicular region.

FIG. 6.—Case 4. Primary calcified complex on left side (not reproduced) and roundish lesion in right mid-zone.

FIG. 7.—Case 5 (March 13, 1940). Faint circular shadow on right in fourth posterior interspace, and "filling" of right costo-phrenic angle (not reproduced).

FIG. 8.—Case 5 (November 4, 1940). Showing definite extension of shadow upwards and outwards.

FIG. 9.—Case 7. Roundish focus in left infraclavicular region with two tiny calcifications (marked C).

FIG. 10.—Case 7. Showing definite increase in size of shadow, six months later.

FIG. 11.—Case 9 (January, 1940). Calcified foci on both sides, with pleural thickening at left base (right upper zone only reproduced).

FIG. 12.—Case 9 (December, 1940). Showing a faint but definite shadow around a group of small calcified foci on right side.

* The views expressed in this paper are those of the author, and do not necessarily represent those of the Middlesex County Council.

lowing a contiguous non-tuberculous process. exacerbation might occur in any of these foci, which could themselves liquefy and cavitate, or, if the exacerbation occurs in the neighbourhood of a small bronchus, the discharge of a large number of bacilli into another part of the lung might give rise to a fresh focus, which would cavitate in due course. Neither of these alternatives seems to happen in the case of the primary pulmonary lesion, but both have been shown conclusively to occur in connexion with the remains of haematogenous disseminations. The apical remains (Simon foci) exacerbate and give rise to infiltrations lower in the lung, which may liquefy and cavitate; and "round foci" exacerbate and themselves cavitate. Another possibility is a new focus that develops as the result of a fresh exogenous infection. No pathological confirmation of this is available, but epidemiological and clinical evidence points strongly to its occurrence. Presumably a focus develops when massive and repeated doses of bacilli are inhaled. The lesion probably regresses spontaneously unless at the same time resistance has been lowered, when the lesion tends to progress to bronchogenic tuberculosis. Yet another possibility for which supporting evidence is scarce is superinfection. The mechanism would then be as follows. The introduction of a fresh massive dose would not itself give rise to a new focus in the lung, but the destruction of the bacilli so introduced would release toxins which could cause exacerbation of healed primary or disseminated foci.

To summarize, it may be stated with some assurance that the two common mechanisms from which arises the early lesion of bronchogenic tuberculosis are exacerbation of residual foci of dissemination and fresh exogenous reinfection with massive doses in people with lowered resistance, but the relative frequency of these two mechanisms cannot be established at present. A third, uncommon, origin is a bronchogenic sequel to a progressive chronic dissemination in the lungs.

Detection of Early Bronchogenic Tuberculosis

It is again stressed that early bronchogenic tuberculosis can be detected only by radiological examination. Evidence for this will be found in the work of Braeuning in Stettin and of Malmros and Hedvall in Lund, both of whom published monographs in 1938 on their findings in students, nurses, and hospital personnel. Braeuning reported on 86 people who presented an abnormal radiological picture within one year or less of having given a normal radiograph; primary infection as a cause of the abnormal shadows seen in the later radiographs could be excluded with reasonable certainty. In no fewer than 50 of the 86 persons no symptoms whatever could be elicited. In 10 of the 86 the interval between a clear radiograph and the development of a focus was not more than three months, so that the question of symptoms could be examined with special care; in no fewer than 6 there were no symptoms whatever. Similarly, in the majority of 43 students and nurses who were tuberculin-positive and gave an abnormal radiograph after an interval following a normal one, Malmros and Hedvall found that the onset of the radiological shadow was not accompanied by symptoms.

It is clear that early bronchogenic tuberculosis will not be detected if one waits until the individual consults his doctor, that it can only be discovered by mass radiological examination of the apparently healthy, and that the most fruitful results will be obtained in those exposed to massive infection or conditions lowering general resistance, such as home and work contacts, medical students, nurses, industrial employees, etc. The method to be used requires careful consideration. If such examinations are merely for the purpose of detecting well-developed bronchogenic tuberculosis in people who delay consulting a doctor or in whom

the doctor fails to recognize this possibility, then any method will do, including miniature radiography and screening. If, however, the mass examination is intended to detect the early focus of bronchogenic tuberculosis, then two conditions are essential—a good radiograph, and repetition of the examination every six months or so: for it is most desirable to have a normal film to compare with, and too long a delay between examinations may allow cavitation to occur before the recently developed focus had been detected.

Diagnosis of Early Bronchogenic Tuberculosis

The recognition of a radiological shadow as one of early bronchogenic tuberculosis is easier if a radiograph and a tuberculin-test result, dating no further back than a few months, are available. When a previous film is not available the shadow must be differentiated from a primary pulmonary focus. Simon foci, round foci of dissemination (Cases 3 and 4), and the healed residua of previously unsuspected bronchogenic tuberculosis. It has been shown that the focus of early bronchogenic tuberculosis is found as often above the clavicle as below it, and that it appears as a group of small foci or a shadow with denser nodules in it as often as in the form of a homogeneous cotton-wool shadow. In the light of recent work the distinction (stressed by the late Fishberg, for instance) between a very benign apical tuberculosis and an acute progressive infracavicular *Frühinfiltrat*, or "early infiltration" (as worked out by Assmann and Redeker), is no longer tenable. In practice what needs to be decided is whether the radiological shadow represents an active lesion. It has already been stated that there may be total absence of symptoms. There may be slight pyrexia; but Braeuning found that in 24 of 43 patients, in whom axillary temperature was recorded several times a day, no pyrexia could be detected. Similarly, in 42 of 75 patients in whom the sedimentation rate was noted the figure was normal, and this series included some patients with early lesions which rapidly cavitated. Again, 7 of 48 patients with definitely active lesions showed a perfectly normal blood picture. Only in a few of his patients were all these three investigations carried out, but in 3 of them they were normal. Similarly, Malmros and Hedvall conclude from their findings in 43 students and nurses that whether the focus begins as a group of small nodules or as a so-called "early infiltration" the sedimentation rate is generally not raised. It appears, therefore, that help in deciding whether the lesion is active or not must often be obtained by noting changes in the radiological shadow after an interval (Cases 5, 6, and 7).

A month seems a suitable interval, since this would generally allow enough time to produce a radiological change, and would as a rule, but only as a rule, not be long enough to allow gross harmful changes to develop, unless the case is already one of those which deteriorate rapidly even under treatment.

As will be shown later, another film after a short interval is also of great help in the management of the case. But if one is to rely on these slight radiological changes the standard technique of the films must be good and uniform, and changes that might be caused by technical differences must be carefully appraised.

Prognosis and Management

An attempt must next be made to estimate the outlook for the lesion. Serial radiographs will have already given some indication of its rate of progression. It will be of immense value to know whether the lesion developed as

a result of lowered resistance and exacerbation of old foci or as a new exogenous infection from massive contact with or without lowering of resistance. When only massive contact is a factor, interruption of this may be sufficient to allow natural regression of the lesion* (Case 8). If lowering of resistance is a factor, then clearly this will not be enough, and measures to increase this resistance, either in the home or in a sanatorium, will need to be taken. It may be very difficult or even impossible to find the incriminating factor or factors, but careful history-taking and investigation of the patients' environment should discover this with reasonable sureness in an important proportion of cases.

The first steps in the management of the individual patient are therefore serial films and investigation of aetiological factors. If the lesion is only doubtfully progressive, or is probably due to massive contact alone which can be interrupted, then it may be justifiable to allow the patient to carry on with his work, more rest in leisure hours being suggested, and monthly investigations with radiographs, sedimentation rates, etc., being continued. If the lesion is definitely progressive, and the factor of lowered resistance cannot be excluded, more is indicated. Before advising institutional treatment, measures short of this must be considered, because reluctance to give up work and leave home for several months is likely to be very great when the patient feels there is nothing the matter with him. When ceasing work is likely to be followed by the necessary restful conditions, good food, and discipline in the home or with relatives, then this home treatment might be tried in the slowly progressive case, provided monthly radiographs and other investigations are practicable. Failing this a stay in an institution is essential.

A digression on tubercle bacilli in the sputum is here necessary. The definition of early bronchogenic tuberculosis excludes radiologically detectable cavitation, but even a tiny focus, if situated in the neighbourhood of a small bronchus, would produce a slight amount of bacilli in any sputum expectorated, even if cavitation had not occurred, and therefore the presence of bacilli in the sputum does not necessarily remove the case from the group of early bronchogenic tuberculosis. On the other hand, the outlook for such a patient is worse, because extension to other parts of the lung is already possible. It may be that even among people with early foci who produce no sputum, bacilli would be grown from the gastric contents of some or many; this requires further investigation. In the American classification of pulmonary tuberculosis "minimal lesions" are defined as: "(a) slight infiltration without demonstrable excavation; (b) a small part of one or both lungs—total volume of involvement, regardless of distribution, shall not exceed the equivalent of the volume of lung tissue which lies above the second chondrosternal junction and the spine of the fourth or body of the fifth thoracic vertebra on one side"; tubercle bacilli may be present or absent. The official classification in this country is so antiquated that it still relies on physical signs and does not appear to recognize the existence of radiography: discussion of it is therefore futile. The presence or absence of tubercle bacilli in association with the early lesion will clearly affect the management of the patient. Thus, to begin with, their presence will indicate institutional treatment in every case.

Institutional treatment may consist of sanatorium regime alone, rest in bed, or rest in bed combined with collapse therapy; bed rest, continued until the lesion is quiescent, should be considered a *sine qua non* of properly conducted collapse therapy. Whatever benefits may be claimed for sanatorium regime alone, this is not justified in the cases discussed here, because it is so vital that the institutional stay of these patients, most of whom feel more or less well and are reluctant to give up work and most anxious to return to it, should be as short as is compatible with

safety. When there is no sputum, or no tubercle bacilli can be detected in the sputum (culture being of course employed), strict rest in bed, continued until there is evidence of quiescence as demonstrated by serial radiographs, sedimentation tests, and blood examinations, is sufficient unless the lesion shows signs of progression. If progression is evident at the end of a month's bed rest, or if there is no definite evidence of regression at the end of, say, two months, then continued bed rest alone is not justified. And to these patients, as well as to those whose sputum is positive, collapse therapy should be applied without delay. There is plenty of authoritative opinion to support this conclusion. Thus the following among American workers may be quoted: O'Brien (1933), Myers and Levine (1935), and John Alexander (1937). O'Brien favours phrenic interruption, permanent or temporary, according to the case. Turner and Collins (1936) show that artificial pneumothorax in these minimal cases is associated with very slight operative risk, that the percentage of cases with a free pleural space and therefore with an effective collapse is very high, and that the results are distinctly worse when the induction of a pneumothorax is delayed even by a few weeks. The general application of pneumothorax therapy for early bronchogenic tuberculosis does imply, however, that the treatment will be carried out both in institution and in clinic by experienced practitioners, or at least under their close supervision, and, if at all possible, by one physician throughout—the one who induced the pneumothorax.

Advice in regard to the treatment of early bronchogenic tuberculosis may thus be summarized: Get on with it at the beginning of the treatment, for as often as not it is the patient and not the physician who decides when it will end.

Mass Radiological Examinations

Unless the early cases of bronchogenic tuberculosis are properly managed and treated, little benefit will accrue from mass radiological examination: 15% of Braeunig's patients were sputum-positive within one year of a normal radiograph; 41% became sputum-positive within a short time of detection. A cavity was visible after a normal radiograph in 1 case within a month, in 7 within six months, and in 15 within a year. (Hence the importance of repeated radiographic examination at intervals of less than a year if infection from open cases to others is to be prevented.) Death took place from the time of a normal radiograph in 1 case within a month, and in 2 within four months. In most cases, however, the development of the disease was slow at first.

From this it appears that while mass radiological examination will be of distinct benefit to individuals and will result in decreasing infection to others, as a method of eradicating tuberculosis it is likely to play a truly effective part only under the following conditions:

1. That the examinations will be carried out extensively.
2. That the method of radiological examination used will be the best available—that is, radiographs will be taken with a satisfactory technique.
3. That re-examinations will be carried out at no longer interval than six months or so.
4. That full facilities will be available for detailed investigation and observation of all cases with an abnormal or suspicious radiograph.
5. That all persons shown by this means to be suffering from early bronchogenic tuberculosis will have proper and adequate institutional treatment.
6. That such treatment will not interfere with the return of the patient to his work and with the economic security of the family during the absence of the breadwinner, housewife, or mother.

To secure these conditions in full would probably necessitate economic and social changes in our community that

* Persistent massive contact in such a case might be harmful not only by influencing this lesion but by giving rise to a fresh lesion which would progress if resistance were subsequently lowered.

would themselves do more than mass radiological examinations to reduce the incidence of tuberculosis.

Case Reports

Case 1.—A girl aged 8. Mother suffers from advanced bronchogenic tuberculosis. Tuberculin-positive; no symptoms; radiograph on May 31, 1939 (Special Plate, Fig. 1), showed coarse miliary mottling in upper half of each lung. Child not seen again till June 11, 1940, when she was stated to be well and had put on 10 lb. There was tiredness, however, and a radiograph (Fig. 2) showed in addition to the miliary mottling a thin-walled irregular cavity in the right upper zone, presumably due to coalescence and liquefaction of some of the larger foci.

Case 2.—A lad aged 16. Seen in a hospital in February, 1939; for unexplained fever: a radiograph on February 15 showed no abnormality, but one taken a week later revealed an opacity to right of superior mediastinum, and the tuberculin test was positive. Diagnosis: primary tuberculous infection with involvement of mediastinal glands. April 12: lymphocytic left pleural effusion; mediastinal shadow smaller. April 25 to June 7: in sanatorium. Radiograph on August 16 (Fig. 3) still showed enlargement of right paratracheal glands and remains of pleurisy at left base. Radiographs November 15 and January 31, 1940, revealed fresh foci at top of left apex, apparently unchanged in this interval, there being no symptoms, and sedimentation rate (S.R.)—Westergren 1 hour—remaining normal. Radiograph July 31 (Fig. 4) showed bilateral bronchogenic tuberculosis with cavitation. (Interval between onset of primary infection and fully developed bilateral cavernous bronchogenic tuberculosis thus not longer than seventeen months.)

Case 3.—A man aged 32, referred by recruiting medical board. Mother suffers from advanced bronchogenic tuberculosis. No symptoms; radiograph October 15, 1940 (Fig. 5), showed round focus with calcified shell in left infraclavicular region; S.R. normal. Radiographs one month and three months later showed no change in appearances of this focus. (Diagnosis: "round focus" of dissemination; calcifying or partly calcified primary focus excluded, as no calcification seen in corresponding hilar glands.)

Case 4.—A girl aged 11. Father died of bronchogenic tuberculosis six years ago; now in contact with brother suffering from advanced bronchogenic tuberculosis. Slight cough; S.R. normal; radiograph, March 6, 1939 (Fig. 6), showed primary calcified complex on left side and roundish lesion in right mid-zone. Admitted to sanatorium for observation: tuberculin test found positive. Throughout stay there and after discharge, radiographs showed no change in appearances of this focus. (Diagnosis: "round focus" of dissemination; it is possible, however, that the focus represented an "early infiltration" which was already quiescent when the girl was first seen.)

Case 5.—A woman aged 33. Intermittent contact until Christmas, 1939, with sister suffering from bronchogenic tuberculosis. History of pain in right side of chest in March, 1939, when she remained in bed for a month. No symptoms; S.R.=15. Radiograph on March 13, 1940 (Fig. 7), showed faint circular shadow on right, in fourth posterior interspace and partly covered by anterior part of second rib, and "filling" of right costo-phrenic angle. April 15: no symptoms; S.R. normal; radiograph, apparently no change. September 10: no symptoms; S.R. normal; radiograph showed some change in shape of shadow. November 4: no symptoms, but had a "cold" a week before; radiograph (Fig. 8) now showed definite extension of shadow upwards and outwards; recommended for sanatorium. (Diagnosis: probably exacerbation of "round focus" of dissemination; note (1) the pleural effusion a year before first seen, (2) the interruption of contact.)

Case 6.—A girl aged 18. Father suffered from advanced bronchogenic tuberculosis (died October, 1940). November, 1938: no symptoms; radiograph showed infraclavicular shadow on left. February, 1939: no symptoms; radiograph, shadow unaltered. February, 1940: no symptoms; weight about the same; radiograph showed increase in size of focus. April, 1940: confessed to fatigue during past two months; no abnormal physical signs in chest; S.R.=16; radiograph showed further increase in infraclavicular shadow. In sanatorium from May to August. September, 1940: no symptoms; radio-

graphically, shadow was "harder" in appearance, indicating fibrosis. (Diagnosis—most likely sequence: (a) healed dissemination with residual small foci; (b) development of "round focus" which remained latent; (c) exacerbation of this focus due to ? superinfection and/or lowering of resistance.)

Case 7.—A man aged 25, referred by recruiting medical board. Two years previously radiographed at a tuberculosis dispensary elsewhere: this radiograph, inspected by me, revealed no abnormality in lung fields. First seen May 23, 1940: slight cough and sputum; radiograph (Fig. 9) showed roundish focus in left infraclavicular region with two tiny calcifications in one part of it; S.R. normal; sputum negative. June, 1940: very slight cough and sputum (negative); put on 2 lb.; S.R. normal; radiograph, apparently no change. August, 1940: no symptoms; very slight sputum (negative); lost 3 lb.; S.R. normal; radiograph, apparently no change. November, 1940: had a "cold" last week; slight cough and sputum; has put on 3 lb.; S.R. normal; radiograph (Fig. 10), when compared with film taken in May, showed definite increase in size of shadow. (Diagnosis: slowly progressive lesion, probably due to exacerbation of tiny round healed foci of dissemination. This case also illustrates the cumulative effect of very small increases in size of radiological shadows.)

Case 8.—A girl aged 17. Mother suffers from advanced bronchogenic tuberculosis and admitted to sanatorium. June, 1939: no symptoms; radiograph showed shadow in right second anterior interspace. July, 1939: radiograph suggests decrease in this shadow. October, 1939: radiograph, shadow smaller and "harder" in appearance. (It was therefore concluded that the shadow on the first radiograph had represented an *active* focus of early bronchogenic tuberculosis.) December, 1939: no symptoms; working. March, 1940: no symptoms; radiograph shows the shadow originally seen replaced by a very few fibrotic strands and nodules. (Diagnosis: early bronchogenic tuberculosis ("early infiltration"), ? origin, regressing without treatment, contact having been interrupted; therefore presumably arose as the result of massive infection without lowering of resistance.)

Case 9 (This case, though not referred to in the text, is included because it is closely connected with the subject of this paper, as it shows the really early stage of a true "relapse").—A woman aged 28. Case diagnosed as pulmonary tuberculosis in 1934, when a radiograph showed "(R.) slight infiltration of upper zone, (L.) infiltration of upper and middle zones with cavity in upper zone"; later admitted to sanatorium, where a left A.P. was induced, which was carried on until December, 1937. Seen in November, 1938, May, 1939, and January, 1940, when on each occasion a radiograph (Fig. 11) showed the same appearances—calcified foci on both sides, with pleural thickening at the left base. When seen in December, 1940, she was feeling fit but had a slight cough; she had lost over 6 lb. since January, and had been working seven days a week; S.R. normal; radiograph (Fig. 12) showed a faint but definite roundish shadow around a group of small calcified foci on the right side. Note: (1) the calcified foci on the right side were not present in the film of 1934, so that they did not represent a healed dissemination, but healed lesions of bronchogenic tuberculosis; and (2) the group of foci around which the recent shadow is seen had themselves changed in appearance. This suggests the diagnosis of recent exacerbation, due to lowered resistance, of a "healed" focus of bronchogenic tuberculosis, the exacerbation having caused some of the calcified foci to be "ejected" or at all events to change in position.

Summary

It is suggested that the term "pulmonary tuberculosis" should be used as implying any active lesion in the lung belonging to any phase in the evolution of tuberculosis, and the use of the term "bronchogenic tuberculosis" be restricted to the common type of bronchogenic disease.

"Early bronchogenic tuberculosis" is defined as the smallest radiologically detectable focus with potentialities for liquefaction.

The two common mechanisms leading to the early lesion of bronchogenic tuberculosis are exacerbation of residual foci of dissemination and fresh exogenous reinfection with massive

doses in people with lowered resistance. Another, uncommon, origin is a bronchogenic sequel to a progressive chronic dissemination in the lungs.

Early bronchogenic tuberculosis is generally *not* associated with symptoms or signs (including sedimentation rate and blood picture), and can be detected only by radiological examination of the apparently healthy, particularly among groups exposed to massive infection or circumstances lowering resistance.

The focus of early bronchogenic tuberculosis must be differentiated from other tuberculous lesions: a primary pulmonary focus, apical Simon foci, "round foci" of dissemination, and the healed residua of a previously unsuspected bronchogenic tuberculosis. It is found as often above as below the clavicle, and appears as a group of small foci or as a non-homogeneous shadow as frequently as in the form of a homogeneous cotton-wool shadow (*Frühlinfiltrat*, or "early infiltration"). Help in deciding whether the lesion is active or not must often be obtained from serial radiographs.

Help in assessing the outlook for the lesion is obtained from serial radiographs and by finding the causative factor or factors; mode of origin, massive contact, and lowered resistance must be considered.

Treatment will depend to some extent on these factors. Treatment in the home may be considered under certain circumstances, but institutional treatment is usually essential.

Rest in bed until the lesion is quiescent is indicated whenever institutional treatment is advised. Collapse therapy should be used in addition when there is no evidence of regression of the lesions within a very few weeks. Reasons for these conclusions are discussed.

The relations of tubercle bacilli in the sputum to the definition of early bronchogenic tuberculosis and the classification of tuberculosis are discussed, as well as the significance of this finding in connexion with treatment.

The importance of mass radiological examinations in connexion with the detection of early bronchogenic tuberculosis is stressed, but the method to be used is critically examined. The conditions under which mass radiological examinations are likely to play a decisive part in the eradication of tuberculosis of human origin are brought forward.

The papers by Hart, Hilton, and Morland deal with tuberculosis in medical students detected by radiological examination. The papers by Schemmel, by Uehlinger, and by Voigtmann deal with "round foci."

J. Fénéon (*Thèse de Paris*, 1940, No. 189) states that it has been well known since Fournier's time that syphilis may give rise to osteo-articular lesions. They are rare, however, and occur in the course of active syphilis. The part played by syphilis in the aetiology of chronic rheumatism is much more important, hydrarthroses and arthritis of the hip-joint being the most frequent manifestations. It is often difficult to determine the existence of syphilis in an old-standing case which has been inadequately treated and may be associated with other infections. Inconstant results are yielded by chemotherapy, which should be employed with caution as the patients are affected by diffuse sclerosis. Orthopaedic surgery is important in the correction of deformities.

EMPLOYMENT OF AIR-RAID NOISES IN PSYCHOTHERAPY

BY

F. L. McLAUGHLIN, M.D., D.P.M.

Major, R.A.M.C.

AND

W. M. MILLAR, M.D., D.Psych.

Major, R.A.M.C.

Specialists in Psychological Medicine at a Military Hospital

A large proportion of patients admitted to a neuropathic military hospital revealed that their neurotic breakdown was either determined or in part precipitated by the unaccustomed stress of noises, such as gun-fire, shell-bursts, exploding bombs, sirens, planes, and dive-bombing. Some of these soldiers were Dunkirk casualties, but the majority were men who had not served outside England. Experience showed that treatment along orthodox psychotherapeutic lines, which included physical training, occupational therapy, route marches, games, etc., was impeded in these cases by too quiet an environment in hospital. While other symptoms had been resolved there remained a certain hypersensitiveness to air-raid noises.

The type of patient who came into this group and who formed the material for the treatment here outlined consisted of those in whom anxiety was the main presenting symptom. Their symptoms were related closely to experiences of a traumatic nature—physical or psychological—when in the "front line." It was considered that a close approximation between hospital life and life in the Army was necessary if these men were to remain well when returned to their units. An attempt was made to "de-condition" the state of hypersensitiveness to warfare sounds by reproducing the disturbing noises till the patients gradually became more normal in their reactions.

Method

At first the apparatus used for reproducing these noises was rather crude, consisting of a small portable field siren and an assortment of tin boxes and sticks. Later, with the helpful co-operation of the B.B.C., it was possible to make use of gramophone records of actual warfare. Technicians made to our specification records of sirens, the firing of A.A. and machine guns, sounds of planes, dive-bombing, and explosions. Individual sounds or a composite effect could be reproduced when required. Records combining reassurance talks with actual bombing noises were also made. The following technique was employed:

The patient was given a simple explanation of the treatment and its object. He was placed in a state of relaxation, and details of the pulse rate, respiration, blood pressure, presence of tremors, restlessness, and the like were recorded. He was then subjected to the particular sound deemed to be the precipitant in his case. Notes were made of changes occurring in the physical and mental state, and after a short rest period the stimulus was again given. Depending on the response obtained, this was repeated three to seven times at each session, at the end of which the mechanism and meaning of fear were explained. The record chart, revealing a gradual improvement in responses—a phenomenon almost invariably present—was shown to the patient after the first session.

Reassurance and encouragement on common-sense lines were given to certain patients. They were told: "Men, women, and children in our badly bombed cities have developed a new lease of life. They are in better mental trim than those in safe areas. They have faced the raids, have found them not so bad as anticipated, and have got over them. They carry on with their jobs

and take a pride in being fit for fire-fighting and other duties. You can do the same, and this treatment will help you to get accustomed to raid noises."

Conditioning and Abreaction

Though the procedure was intended to be a means of "conditioning" cases to noxious sounds, it soon became evident that it could be used as a speedy and practical method of abreacting patients. The process of letting a patient re-live terrifying emotional experiences has a therapeutic effect. As a measure for producing abreaction the employment of war noises is much simpler than hypnosis or hypnarcosis. It is quick, effective, and does not demand too great technical skill. The patient is enabled to recall terrifying incidents which had determined his symptoms, and by expressing them in the secure atmosphere of the hospital his self-control and confidence are helped. The following case illustrates the use of the method as an abreactive agent.

A private aged 22 who was in good health until shelled badly in France developed acute anxiety symptoms, thereafter tending to become worse when in bombing raids in this country. After admission to hospital he was given a course of "sound-therapy," and on the first application he became very agitated, volunteering the information that the noise "brought it all back again." The blood pressure and pulse rate showed marked increase after hearing warfare noises. Though the patient was aware that the sounds were artificial, he reacted briskly when the stimulus was given, vivid memories of the initial traumatic experience being recalled.

It was established in a number of cases that this procedure could easily reveal a wealth of psychological material, and by releasing emotional tension have a beneficial effect.

Some people cannot stand up to the stress of noises without help. It is not a question of "scrimshanking" but of constitutional make-up. They can be helped by realizing that knowledge and a sense of security will see them through. Giving them sane simple explanation and advice and getting them accustomed to disturbing stimuli increases their stability and sense of security and relieves apprehension and exaggerated fears. Our experience would indicate that the repetition of noxious stimuli is of value in restoring function in these cases. The principle of conditioning is very much that of the horseman who mounts immediately after a fall in order to prevent the association of fear and riding.

One man who complained of trembling, palpitation, and loss of control during air raids since the Dunkirk evacuation was conditioned to warfare noises in a week, and during subsequent air-raid alerts was no longer disturbed, being finally discharged to duty. Another soldier, with a similar history, at first reacted so strongly to the sounds given that he rushed screaming from the room. At the end of six days' treatment he was perfectly calm and showed no reaction whatever.

Conclusion

Air attack is being employed on all fronts to demoralize our people. It is now evident, however, that the anticipated number of psychiatric casualties as a result of air raids has not been justified. Actually there has been no increase in the incidence of neurosis or psychosis in our bombed cities. A corporate sense of discipline, preparedness, and individual effort has maintained morale. Fear has to a large extent been dissipated by the activity of fire-fighting and other defence measures. Fear, which is simply a normal protective instinct, can be countered by enlightenment, and aerial bombardment is unlikely to achieve its demoralizing object if the experience is not a complete surprise. Apprehension and anxiety concerning air raids are more likely to affect those who are inactive and have

not been accustomed to warfare noises. Repetition of bombardment noises would appear to assist in raising the power of endurance and in enabling the individual to stand up to this new form of attack.

Our thanks are due to various members of the B.B.C. staff for their valuable help in producing the records used in this investigation. We are also indebted to Colonel G. W. Will, O.B.E., for permission to investigate cases under his care.

CHEMOTHERAPY IN ACUTE MIDDLE-EAR DISEASE: "MASKED MASTOIDITIS"

BY

C. A. HUTCHINSON, F.R.C.S.Ed.

Major, R.A.M.C.; Otologist to a Military Hospital

I have recently had three cases (quoted in detail below) referred to me in quick succession which have much exercised my mind on the subject of chemotherapy in acute disease of the middle ear.

In view of Dr. J. B. Jessiman's (1941) article on the subject, which drew forth prompt criticism from Mr. Lionel Colledge (1941), it would seem that there is ample justification for uttering a warning against putting too great reliance on drugs of the sulphonamide group. They have admittedly proved of marked value in the control of infections of the middle-ear cleft, but it is a mistake—which may have tragic consequences—to assume that, quite irrespective of whether myringotomy has or has not been done, all is of necessity well with the patient because the temperature has fallen, mastoid tenderness has disappeared, and the other symptoms and signs have cleared up. Such cases, indeed, call for very careful watching, since the sulphonamides can "mask" a mastoiditis most effectively, while serious complications may develop in the most alarmingly sudden manner.

Furthermore, it should be noted that in each of the cases quoted below sulphapyridine has been employed. Now, this agent is excellent for pneumococcal infections, but even its most enthusiastic supporters must admit it to be of very considerably less value than sulphanilamide where the infection is of streptococcal origin. After all, pneumococci are, it is true, responsible for many cases of middle-ear infection, but a number of cases are undoubtedly due to streptococci or other organisms. We should therefore be on our guard against thinking as it were in terms of sulphapyridine to the exclusion of sulphanilamide. Such blind faith can only result in a proportion of failures, and these will inevitably bring quite unwarranted discredit on a group of most valuable therapeutic agents.

It is suggested that the correct procedure in every case of threatening or frankly developed middle-ear infection is to take swabbings from the tonsils, nasopharynx, and/or purulent discharge itself (whether the result of perforation or myringotomy) and, if bacteriological examination reveals the presence of streptococci, then sulphanilamide (and not sulphapyridine) should be administered. It is only by such conscientious use of the appropriate member of the group that we can secure more consistently satisfactory results and so gain for these agents that confidence in them which is their just due.

Lastly, while agreeing with most of the relevant comments by Mr. R. Thomas (1941), I cannot find myself in agreement with his expressed wish that "the day will soon come when this simple operation [he specifies "paracentesis"] will become part of the armamentarium of every general practitioner." In the first place, paracentesis has been rightly

displaced from favour by the far more effective procedure of myringotomy; and, secondly, "every general practitioner" does not possess the experience and nicety of judgment which alone can decide whether myringotomy still has a reasonable chance of averting an acute mastoid or whether things have already gone too far for anything short of immediate mastoidectomy to have a hope of relieving the condition and possibly preventing a catastrophe.

Case I

A gunner aged 22 was admitted to a military hospital on January 17, 1941, with a history of left otalgia followed by otorrhoea. Temperature 99.4°, pulse 80. "Exacerbation of an old C.O.M.S.(L)" was diagnosed. Next day temperature tended to swing between 100.6° and 97.4°. On the 19th it settled to normal, and he was given guttae glyc. and phenol, fomentations, s.v.r. drops, and mist. aspirin. He was discharged to a convalescent home on the 25th, with normal temperature but profuse otorrhoea. From January 28 to 31 sulphapyridine, 1 gramme four-hourly, was given. Temperature was very slightly irregular above and below normal. He was transferred to a convalescent depot on February 7.

On February 10, when referred to me, there was thin somewhat offensive left otorrhoea, slight deafness in the left ear, medium-sized postero-inferior perforation, but no vertigo or tinnitus. He was returned to the convalescent depot with the recommendation that he be kept under close observation and that dry mopping and insufflation of 1% iodoboric powder be carried out. On the 13th he was readmitted to hospital with general malaise and severe pain behind the left ear. Otorrhoea was profuse and the left ear was pushed somewhat forward; there was no mastoid tenderness, but the patient looked ill. Subacute left mastoiditis was diagnosed. The next day left epitympano-mastoidectomy was performed. Very extensive involvement of the mastoid region was found. The bone was of mixed cellular and sclerotic type. Aditus, attic, antrum, and cells contained pus under some pressure. Healing by first intention was secured, and recovery was uneventful; the otorrhoea soon dried up, and there was very little loss of hearing.

Case II

A lance-corporal aged 21 was referred to me at a military hospital on January 21, 1941, with a history of having first noticed left-sided otorrhoea while on leave. There was slight deafness, but no pain; trismus, said to date from the extraction of a left lower wisdom tooth, was present. He stated that he had been treated by a civilian doctor and given, among other things, tablets of sulphapyridine, but no details as to dosage, etc., were available. He looked ill. There was a moderate amount of thin non-offensive otorrhoea, left cervical adenitis, and medium-sized postero-inferior perforation, but no mastoid tenderness.

He was admitted and kept under close observation, with dry mopping of the otorrhoea, counter-irritation over the cervical glands, gargles, and mentholization. During the next few days the trismus improved, but the temperature showed a slight tendency to swing between 98° and 99°. In the afternoon of January 26 there was a sudden exacerbation, with malaise, swelling of the left parotid region, slight left facial paresis, and gradual filling up of a fluctuating swelling on the posterior aspect of the lobule of the left ear. On the 27th he had a definite toxic appearance; the above-mentioned swellings had increased and the left facial paresis had deepened. Temperature normal; pulse 98. Left epitympano-mastoidectomy was performed. There was generalized osteomyelitis in an acellular mastoid with a perforation near the tip, "tracking" into the lobule of the ear and into the parotid region. This was thoroughly cleared and the wound packed open, secondary suture being performed on February 5. The wound then healed by first intention, the facial paresis recovered completely, the otorrhoea dried up, and the perforation in the drum healed. The hearing is good.

Case III

A second-lieutenant aged 28 was admitted to a hospital on February 18, 1941, with severe otalgia in the left ear of sudden onset and a history of acute left otitis media two years previously. Slight pulsatile left otorrhoea was present, but no

mastoid tenderness. Sulphapyridine and a spirit-and-flavine wick were used, and on March 11 he was given a week's sick leave, the ear being then dry and all symptoms relieved. On March 15 diplopia developed, and on the 18th he consulted the eye specialist, who referred him to me. He gave the following history: For some days he had had fairly severe neuralgic pain centred somewhat vaguely between the left ear and the left eye, which had gradually changed to a dull ache behind the left eye; then on the 15th, as stated above, he had for the first time noticed the diplopia. On examination I found complete paralysis of the left external rectus; in other words, he presented the complete picture of the Gradenigo symptom-complex, indicating the presence of petrositis. A small perforation was found in the anterior portion of Shrapnell's membrane, from which a thin trickle of pus was escaping. Radiographs showed considerable relative radio-opacity of the left mastoid region and the petrous pyramid, with loss of the cellular outlines.

A left Schwartz mastoidectomy was performed on March 21. There was widespread involvement of the mastoid cells, which contained pus, while the mucosa was thickened. Two polypi were impacted in the aditus, and on their removal pus under considerable pressure escaped from the attic region and the middle ear. Healing took place by first intention, and convalescence was uneventful. All symptoms have been removed, while with the assistance of electrical stimulation of the paralysed muscle complete recovery from the paralysis has been secured and the diplopia has disappeared. The perforation in the drum has healed and the hearing seems to be normal.

Medical Memoranda

Intestinal Haemorrhage as a Complication of Sulphonamide Therapy

The recent occurrence of melaena in two children under treatment with sulphonamide drugs stimulated an inquiry into the recorded incidence of this complication. The scanty references in the literature and the absence of records of its occurrence in this country make these notes and observations of value.

CASE REPORTS

Case 1.—A boy aged 5 was admitted to the Southport Infirmary on January 23, 1941, with a history of severe vomiting of two days' duration. Lumbar puncture produced 4 c.cm. of turbid fluid from which meningococci were later grown on culture. Next day he was given 0.5 gramme of sulphapyridine soluble intramuscularly and transferred to the borough isolation hospital. On admission he was drowsy and irritable, and the temperature was 98.4° F. He did not appear to be very ill. Soluseptasine 0.5 gramme intramuscularly was ordered four-hourly. Next day after five injections his temperature had remained normal, but head retraction and opisthotonos were pronounced. Lumbar puncture produced no fluid, and cisternal puncture only 2 c.cm. of opalescent fluid. Sulphapyridine soluble 0.5 gramme intramuscularly was ordered three-hourly. On January 27 the boy was much improved and took 0.5 gramme of sulphapyridine by mouth four times daily for four days. On January 31 he appeared normal, and received three 0.5-gramme doses of sulphapyridine, and on February 1 two doses of 0.5 gramme each. In the night of February 1 he passed a small tarry motion, and on February 2 two large melaena stools. He was very pale, but his condition did not give rise to anxiety. Parenteral salines were given. As we were unable to account for the melaena a blood film was made late at night and suggested a diagnosis of myeloid leukaemia. The temperature was 99° F., the spleen was not palpable or enlarged to percussion, the liver was not enlarged, no enlarged glands could be felt, no petechiae were seen, the urine was normal, and there was no evidence of jaundice. The blood film, however, showed a considerable increase of white cells, estimated at more than 100,000, of which 92% were polymorphs, 6% myelocytes, and 2% lymphocytes. The red cells were rather pale, and showed anisocytosis; 2% nucleated red

cells were found. Unfortunately the cell counts were deferred until next day and the child collapsed and died suddenly during the night.

Case 2.—A girl aged 8 was admitted to the Southport Infirmary on February 12, 1941, with a history of headache and vomiting of a few hours' duration. Lumbar puncture produced 6 c.cm. of opalescent fluid from which meningococci were later grown on culture. The child was admitted to the borough isolation hospital the next day, after receiving an intramuscular injection of 1 gramme of sulphapyridine soluble and 1 gramme of sulphathiazole by mouth. On admission she was very listless and semicomatose, temperature 100.4° F. Sulphathiazole 1.5 grammes was ordered four-hourly. The temperature became normal the next day and did not rise above 99° F. thereafter. On February 14, following difficulty in swallowing, 1 gramme of sulphapyridine soluble was given intramuscularly four-hourly, followed by sulphathiazole 0.75 gramme four-hourly for three days. On February 18 the child did not appear well and seemed more comatose. Seven grammes of sulphathiazole was given in the next twenty-four hours, when it was finally stopped. On February 20 she passed a small melaena stool, but remained well and did not complain. A blood film appeared normal and a white cell count totalled 14,200. On February 21 another final melaena stool was passed, and the child thereafter progressed satisfactorily until discharge on March 10.

DISCUSSION

In neither child was there a history of a tendency to bleed and the family history in each case was negative. In Case 1, apart from the abnormal findings in the blood film, there were no clinical signs to suggest that the child was suffering from myeloid leukaemia, but the melaena was originally attributed to this possibility in the absence of any more feasible explanation. The occurrence of melaena in Case 2 gave reason to the consideration that the bleeding in Case 1 had been due in large part at least to the sulphonamide drugs.

Long and his associates (1940) report the rare occurrence of hyperleucocytosis during sulphanilamide and sulphapyridine therapy, generally in the presence of acute haemolytic anaemia, of which there was no evidence in this case. They also report that unexplained bleeding from the gastro-intestinal tract has been seen in one or two cases of sulphanilamide and sulphapyridine therapy, and that one patient who received sulphapyridine had bleeding severe enough to cause death. They record no instance of gastro-intestinal bleeding following sulphathiazole. Blake recorded two instances of gross intestinal haemorrhage in patients receiving sulphanilamide, in neither of whom was there any other plausible explanation for the untoward reaction.

These two records of melaena occurring among a comparatively small number of patients receiving sulphonamide drugs may stimulate the interest of others with greater experience and better facilities for investigation and lead to a better knowledge of its true incidence.

F. E. CRAWLEY, M.D., D.P.H.,
Deputy M.O.H., Southport C.B.

REFERENCES

Long, P. H., et al. (1940). *J. Amer. med. Ass.*, 115, 364.

H. D. Wright (*J. Path. Bact.*, 1941, 52, 237), in a record of the three types of *C. diphtheriae* in 8,040 cases of diphtheria in Liverpool during 1937-40, states that this period was marked by a notable increase in the number and proportion of *gravis* cases. There was a slight decrease in the proportion of cases in the age period 5-9 years. The difference in age incidence between the different types was slight. The case fatality was highest in the *intermedius* infections, particularly among the older children, and lowest in the *mitis* group. The greatest number of deaths were due to the *gravis* type. Deaths from toxæmia predominated in the *intermedius* and *gravis* infections and from pneumonia or respiratory involvement in the *mitis* infection.

Reviews

HARDY ANNUAL

The Medical Annual, 1941. A Year Book of Treatment and Practitioner's Index. Fifty-ninth year. Editors: H. Letheby Tidy, M.D., F.R.C.P., and A. Rendle Short, M.D., B.S., B.Sc., F.R.C.S. (Pp. 516; 39 plates, plain and coloured. 25s. net.) Bristol: John Wright and Sons, Ltd.; London: Simpkin Marshall, Ltd.

This valuable work, as its devotees know, is published by Messrs. John Wright at Bristol, a town that has borne the full brunt of enemy attacks from the air. The publishers and the editors have not, however, been deterred by what must have been considerable difficulties, and both are to be congratulated on maintaining the standard of the familiar green-covered volume. There is one small criticism that we would make. In a yearbook that is primarily meant for the general medical reader we doubt whether there is much point in including special plates illustrating, for example, the prevention of elephantiasis chirurgica, seminoma of the testis, an operation for persistent thyroglossal duct. The illustrations are, as usual, very well reproduced, and there are a number of excellent line drawings in the text.

It is impossible to refer in detail to the numerous items, arranged in encyclopaedic form from A to Z. The article on vaginal thrush is accompanied by two instructive half-tone illustrations: a long and helpful article on electroencephalography is contributed by Mr. Grey Walter and Prof. F. L. Golla; the two editors—Dr. Letheby Tidy and Prof. Rendle Short—contribute articles on the medical and surgical aspects respectively of abdominal disorders; Prof. R. M. F. Picken describes schistosome dermatitis, which so far has been found to occur in one place only in Great Britain—Roath Lake, Cardiff. The common and the uncommon all receive skilful treatment at the hands of practised commentators.

STATISTICAL STUDIES OF TUBERCULOSIS

Studies on Tuberculosis. Four Papers by Different Authors. The American Journal of Hygiene Monographic Series, No. 16, 1941. Baltimore: The Johns Hopkins Press. 1941. Publication financed by the Rockefeller Foundation, New York City.

This monograph is devoted to four papers describing two series of epidemiological investigations.

Eugene L. Opie, Persis Putnam, and E. Joyce Saward portray the spread of tuberculosis in negro families of Jamaica, B.W.I. The disease follows a much more rapid course than in the white people of European extraction, and is readily transferred from the first sufferer in a family to other members of the household, adults as well as children, so that many of them may die within two years after the disease has been introduced into the family. The proportion of those with tubercle bacilli in the sputum is much greater than among white persons of the United States, and greater than among American negroes. This factor and uncleanly habits, unhygienic housing conditions, and lack of facilities for segregation all promote the spread of disease in Jamaica. Though the tuberculin reaction in Jamaica, as elsewhere, has little value as an index of manifest disease, the frequency of lesions visible radiographically and of manifest disease increases with intensity of reaction. From what has already been said, it may be anticipated that asymptomatic and latent lesions were found much less often in Jamaican negroes than in white adults (and even less frequently than in American negroes). The authors conclude that the high level and rising incidence (with age), frequency, and mortality from tuber-

culosis in the Jamaican adolescents and adults following exposure to the disease occur as the result of exogenous infection.

A. H. Graham, P. W. Auston, and Persis Putnam made a survey of tuberculous infection in a rural area of East Alabama, and traced the fate of persons exposed to tuberculosis in white and negro families. Manifest tuberculosis among negroes was found to begin earlier, run a shorter, sharper course, and more often end fatally than among white persons. These were characteristic differences, as was the higher frequency of latent tuberculosis among white persons—that is, among negroes lesions were more likely to progress to disease and death; among white persons there was more tendency toward healing and calcification. The authors do not doubt that tuberculosis spreads from persons suffering with the disease to those in contact with them; that this is true of persons whose exposure begins in adult life as well as those first exposed in infancy, childhood, or adolescence; and that exogenous infection occurs in rural as well as in urban areas.

These elaborate, carefully worked out statistical studies illustrate once more the importance of natural resistance in tuberculous infection, and the role of exogenous infection in the incidence of manifest tuberculous disease at all ages in people with low natural resistance. In our opinion it would, on the other hand, be unwise to assume that the latter holds good to an equal degree in regard to pulmonary tuberculosis in adults among the more resistant European communities.

PRACTICAL ORTHOPAEDICS

Orthopedic Surgery for Nurses, including Nursing Care. By Philip Lewin, M.D., F.A.C.S. Third edition, revised and reset. (Pp. 462; illustrated. 17s. 6d. net.) Philadelphia and London: W. B. Saunders Company. 1941.

Orthopaedics is a specialized branch of surgery, but its principles can never be divorced from those of general surgery. In this country nurses usually receive their orthopaedic training before their general training, and in consequence the teacher of orthopaedics labours under the disadvantage of having students with little or no knowledge of pathology and general surgical principles. It is essential that the student-nurse should build her storehouse of knowledge not on the shifting sands of current orthopaedic practice but on the rock of general surgical principles. The ideal textbook must first discuss the anatomy, physiology, and pathology of the framework of the body, and the principles of the surgery of wounds, infections, and deformities must be clearly enunciated. This textbook fails singularly in this respect, and is concerned rather with the accumulation and tabulation of a vast amount of detail more suitable for a medical graduate. For instance, should any student-nurse be expected to know the thirty-seven differential diagnoses for tuberculous disease of the spine as listed on p. 150? Again, in the chapter on the orthopaedic operating room, though the author sets out in detail many aspects of theatre routine, he does not mention the reasons for and principles of asepsis. Further, in the chapter on fractures, one of the least commendable in the book, the three cardinal principles of treatment are obscure, and there is practically no mention of compound fractures. However, such criticism may be unjust, since the book is primarily intended for American use, where the nurse may already have been well grounded in general surgery.

For a graduate-nurse or medical student this book has a great deal to commend it. Its chapters are well arranged and the material is up to date, even such matters as arthrograms for congenital dislocation of the hip and plasma transfusion for shock being mentioned. The book contains a wealth of practical detail, particularly in the chapter on

orthopaedic nursing care. The chapters on poliomyelitis are excellent and deal with the subject more thoroughly than any English textbook, and here the principles of treatment are clearly explained.

This book of almost 450 pages covers the whole field of practical orthopaedics and includes over 200 well reproduced diagrams and illustrations.

PSYCHOLOGY OF BREAST-FEEDING

The Nursing Couple. By Merrell P. Middlemore, M.D. With an introduction by Edward Glover, M.D. (Pp. 195. 7s. 6d.) London: Hamish Hamilton Medical Books. 1941.

When psychologists make assertions about infant feeding, paediatricians and obstetricians are apt to feel that enthusiasm is proving more of a stimulus than experience. For this reason the late Dr. Merrell P. Middlemore's book on *The Nursing Couple* is of great value, for here is a medical practitioner, trained as an obstetrician and as a psychologist, recording her observations and conclusions as a result of studying the behaviour of newborn babies at the breast in a hospital ward, and hence, possibly for the first time, it is likely that some of the truth on this important subject has been set down with scientific accuracy. That psychological factors enter into breast-feeding, successful and unsuccessful, is well recognized, but Dr. Middlemore's painstaking analysis sets out in some detail what these factors actually consist of, and all concerned with breast-feeding will learn much from a close study of the book. It clearly emerges that the nurse is the dominating figure in the successful establishment of lactation. Too stern a technique, too rigid a programme, and a lack of sympathetic understanding of the emotional background of the nursing couple—mother and baby—spell failure. It is equally clear that some sort of programme is necessary, and it is enthusiasm rather than experience that has led Dr. Edward Glover in his introduction to suggest that all will be well if babies are fed when they are hungry. It is just such lack of "discipline" that led the late Sir Frederick Truby King to initiate his great work—for as superintendent of a mental home he saw the wrecks produced by the absence of some sort of order in the nursery. Dr. Middlemore's book should certainly be read by all doctors and midwives, and much of its contents will help the expectant mother.

Notes on Books

Control of Pain in Dental Practice, edited by Dr. J. L. T. APPLETON (Lippincott, 15s.) contains a series of articles by different contributors which deal with the innervation of the teeth, local anaesthesia and general anaesthesia. The contributors are members of the medical and dental schools of the University of Pennsylvania. An article by Dr. H. Prinz on the early history of pain control in dentistry is of special interest because the medical profession owes to the dental profession the discovery of the use of nitrous oxide and ether as anaesthetics. In a chapter on the pharmacology of drugs, Prof. C. F. Schmidt gives an interesting summary of the advantages and disadvantages of intravenous anaesthesia.

Medical Organization and Surgical Practice in Air Raids (J. and A. Churchill, 12s. 6d.) first appeared in March, 1939. It has since been reprinted twice, and the authors, Brigadiers P. H. MITCHNER and E. M. COWELL, have now brought out a second edition. Between the two editions the war has happened, and the first two chapters, both dealing with air raids, have consequently been rewritten in the light of bitter experience. Other chapters have also been revised to include, for example, further information on the sulphonamides and the use of blood plasma. Mitchner and Cowell are sure guides to the many problems embraced by the title of their book, and the second edition deserves the success that attended the publication of the first.

EQUINE ENCEPHALOMYELITIS

It is becoming only too obvious that in order to unravel the many problems associated with virus diseases one must be, among other things, a highly competent field naturalist. African horse sickness, for instance, can remain latent in an area for many years in the absence of all Equidae, though how or where it remains latent is unknown. Yellow fever, it seems, can somehow maintain itself in the absence of all human beings; infection of man is, in fact, merely an unfortunate incident in the life history of a virus that primarily exists as an inapparent infection of animals. There are much the same lacunae in our knowledge of what has been called, somewhat unfortunately, "equine encephalomyelitis." For some years past a very fatal encephalomyelitis of horses has been recognized in the New World, from Canada to the Argentine. Cases are seen chiefly in the late summer and autumn, and in some years enormous epizootics occur: in 1938 in Minnesota alone there were 23,686 cases in horses, with 4,979 deaths. The problem of equine encephalomyelitis was complicated at the outset by the discovery made by Ten Broeck and Merrill¹ that there exist in the U.S.A. two strains of the virus which are immunologically quite distinct. These two strains are known as the eastern type and western type respectively, the Appalachian Mountains forming a rough dividing line. The symptoms and the pathological changes caused by the two viruses are, however, closely similar both in horses and in experimental animals, except that the disease is more fulminating when caused by the eastern strain. Both viruses are of the same size as determined by differential filtration and centrifugation, while both are quite distinct from the causal agent of European equine encephalomyelitis, Borna disease, as well as from the virus of a Russian form of equine encephalomyelitis, which is most probably an atypical rabies. An Argentine strain, however, was identical with the Western American virus; but a Venezuelan strain, on the other hand, examined by Beck and Wyckoff,² was immunologically different from both American strains, though perhaps remotely related to the eastern virus. Thus at least three distinct immunological strains of the equine encephalomyelitis virus exist in the New World. Now, as is well known, after exhibiting a long geological succession all Equidae suddenly died out in America at the end of the Pleistocene Period. They were not reintroduced until the time of the Spanish conquest. The question therefore arises whether the various strains of equine encephalomyelitis virus have arisen since the discovery of the New World by Columbus, or

whether they have lived in other hosts, causing inapparent infections. The first step in the elucidation of this problem was the discovery that both the eastern and the western viruses could be transmitted by mosquitoes under laboratory conditions. While the eastern strain is transmitted by *Aedes cantator*, a salt-marsh mosquito, the western variety is transmitted by *A. aegypti*, *A. vexans*, *A. atropalpus*, *A. triseriatus*, *A. nigromaculis*, *A. taeniorhynchus*, and *A. albopictus*. *A. sollicitans* transmits both strains.

Although equine encephalomyelitis tends to occur in the late summer and autumn, no mosquito has actually been found infected under natural conditions, the same being true also of *Dermacentor andersoni*, a tick which Syverton and Berry³ have found capable of transmitting the western strain of the virus. A fresh complication arose when it was found that both the eastern and the western strains were causing a highly fatal encephalomyelitis in man in some outbreaks, as in Saskatchewan in 1938 in the absence of mosquitoes. The first case was described as long ago as 1930 by Meyer, Haring, and Howitt,⁴ but it was only in 1938 that it became evident (cf. Fothergill *et al.*,⁵ Feemster,⁶ Webster and Wright,⁷ and Howitt⁸) that a very considerable number of infections were occurring throughout the United States, more especially in children. Many of these were fatal, but Farber and his colleagues,⁹ Davis,¹⁰ and Platou¹¹ have more recently described cases with residual paralyses, mental changes, and other nervous sequelae. Shortly after human cases had been described in the New England States, Tyzzer, Sellards, and Bennett,¹² and later Van Roekel and Clark,¹³ and Beaudette¹⁴ all isolated the eastern virus from wild ring-necked pheasants, while Fothergill and Dingle¹⁵ obtained the same virus from wild pigeons. Whether pheasants and pigeons form the only reservoir from which horses and men can be infected remains uncertain. Under laboratory conditions a very considerable number of wild birds and rodents such as voles, rats, and mice can be readily infected, while many wild and domesticated birds either succumb or carry the virus in their blood even though they fail to show clinical symptoms (cf. Davis¹⁶ and Howitt¹⁷).

It is obvious that transmission of the infection, possibly by mosquitoes, to horses and man represents but a part of the story: the lacunae can be filled in only by intensive oecological studies. So far observations have yielded largely negative results; Howitt,¹⁸ for instance, in California failed to isolate the virus from the brains of forty-three wild animals and birds, representing fourteen different species. Davis,¹⁹ however, brought forward evidence that birds such as the domestic sparrow, pigeon, and cow-bird can acquire the virus by the bite of infected mosquitoes, and that infected birds may serve as a source from which mosquitoes can become infected. Broeck,¹⁸ it is interesting to note, found neutralizing antibodies in the sera of fowls from farms where horses had died from encephalomyelitis. There is thus suggestive evidence that birds may possibly serve in nature as alternative hosts for the virus of equine encephalomyelitis. Mammals may also play a similar part. Syverton and Berry,¹⁹ in 1936, found that Richardson's ground squirrel, *Citellus richardsoni*, was highly susceptible to the western strain of the virus of equine encephalomyelitis, while one specimen was refractory to inoculation and presumably immune. In 1940 Gwatkin and Moore²⁰ showed that the brains of certain of these ground squirrels from Alberta harboured the virus. No virus was, however, found by Gwatkin²¹ in some hundreds of ticks, *Dermacentor andersoni*, but Kitselman and Grundman²² have recently reported isolating the virus in Kansas from assassin bugs, *Triatoma sanguisuga*. Thus by studies in various parts of America the full story of the equine encephalomyelitis virus is being gradually revealed.

EFFECT OF CARBOHYDRATE ON PROTEIN METABOLISM

It is seldom that experiments in metabolism are performed first on human beings and later on animals. This, however, has been done by Cuthbertson and Munro^{23 24 25} in their investigation of the influence of carbohydrate eaten at the same time as protein or at a different time. Early observations showed that when carbohydrate is eaten at the same time as protein, and the calorie content of the diet is in excess of energy requirements, there is storage of nitrogen and sulphur, more especially when the excess calories are in the form of carbohydrate rather than of fat. Larson and Chaikoff,²⁶ working on dogs, found that to get this effect the carbohydrate must be taken less than four hours before or after the protein meal. Cuthbertson and Munro,²⁵ continuing their observation on human beings, found that a negative nitrogen balance of some 2 grammes daily was produced by eating the carbohydrate and protein moieties of an adequate diet separately over short periods of time. The nitrogen was lost mainly in the form of urea and was equally distributed between the day and night portions of the urine. If a part only of the dietary protein was dissociated from the carbohydrates the nitrogen balance was undisturbed. If carbohydrate in excess of energy requirements was ingested over long periods, storage of nitrogen and sulphur resulted whether the carbohydrate was taken with or separately from the protein.

Krebs²⁷ has observed that deamination by liver slices is inhibited in the presence of easily oxidizable substances such as lactic, succinic, and α -keto acids (but not glucose), and Cuthbertson and Munro suggest that when carbohydrate is ingested with protein it may yield a more active form of glucose within the body, and thus

ensure that some of the amino-acids escape deamination and go to replace the effete products of endogenous metabolism. Thus nitrogen balance is attained. A surfeit of carbohydrate may save even more amino-acids from the deaminases, with the result that the storage depots are further charged with protein. More prolonged surfeit feeding of carbohydrate seems to result in a storage of carbohydrate also. Nitrogen balance on an ordinary diet in which the proportions of carbohydrate and protein vary is probably attained through the mechanism of storage and depletion of carbohydrate stores as needed. If all the protein is ingested separately from the carbohydrate, the deaminases are free to break down the amino-acids, and the excreted nitrogen consists of that taken in as protein plus the daily endogenous nitrogen.

To gain more exact information Cuthbertson and Munro²⁵ have experimented on rats. They fed four adult male rats, each of about 300 grammes in weight, on a diet of dried egg yolk (12%), dried egg albumen (6%), uncooked potato starch (17%), uncooked rice starch (40%), cane sugar (10%), butter (10%), De Loureiro's salt mixture (1931) (5%), Brewer's yeast extract 2 c.cm. daily per rat, and cod-liver oil two drops per rat per day. The mean daily intake per rat for seven days was 17.5 grammes. During the next twelve days the diet was separated into two fractions: fraction A consisted of the potato starch, rice starch, cane sugar, cod-liver oil, yeast extract, and half the butter and salt mixture; fraction B consisted of dried egg yolk, dried egg albumen, and half the butter and salt mixture. The A fraction (carbohydrate plus fat) was given freely at 8.30 a.m. each morning and the residue removed and weighed at noon. Of the B fraction (protein plus fat) 4.0 grammes were given to each animal at 4.30 p.m. each day, and the meal was always eaten within a few hours. After the first five days of this diet the rats were weighed fasting. During the next seven days they lost weight (average 7.0 grammes per rat), and their output of urinary nitrogen was 0.165 gramme. They were then given the A and B fractions mixed in amounts equal to the mean value of the daily intakes in the previous period. There was an average gain in weight of 5 grammes, and the daily output of urinary nitrogen fell to 0.145 gramme (with a mean difference from the average of 0.02 gramme). The experiment was then repeated on young rats (weighing about 66 grammes). They were first fed on a diet similar to that already described, and then one in which the protein part consisted of ashless casein (12 parts) and dried egg albumen (6 parts) only, the whole of the fat (as lard) and salt mixture being incorporated in the carbohydrate part of the diet. The "paired feeding" technique was followed—that is, each rat in the group receiving the two parts of the diet mixed together was given an amount equal to that which its "opposite" had eaten the previous day. This was particularly important, for the rats receiving the portions separately lost appetite for the carbohydrate fraction though not for the protein. In both experiments there was practically no difference between the average increases in weight of the two groups of rats, though these were below the increase

in weight of a group in the second experiment given an unrestricted mixed diet. In the second experiment, where nitrogen output was measured, the rats receiving the food fractions separately lost 0.0928 gramme of nitrogen, and those receiving the mixed fractions lost 0.0930 gramme. Thus the metabolism of protein in the young rat apparently remains unaffected by separating the protein from the carbohydrate moiety of the diet. It does, however, reduce the appetite, which is reflected in a small increase in body weight. The behaviour of the adult rat corresponds with that of the adult human being—namely, when protein and carbohydrate are eaten separately there is a small loss of nitrogen and also of body weight.

X-RAY INJURY AGAIN

Although the harmful effects of x rays on living tissues were noted within a few months of Röntgen's "preliminary communication," it was not until about 1903 that some consideration was given to the dangers to which those working with x rays might be exposed. Protective clothing and other devices made their appearance, but there were no satisfactory means of judging their efficacy. The first organized move towards protection against x-ray injuries was made by the British Röntgen Society in 1915, but the medical conscience was not generally aroused until a number of deaths occurred from aplastic anaemia in 1920 and 1921. In the latter year the British X-ray Protection Committee published the first set of protective recommendations; it stressed the importance of protection at the first International Congress of Radiology held in London in 1925, and three years later persuaded the second Congress to form an International X-ray and Radium Protection Commission, which subsequently adopted the British recommendations almost verbatim. It speaks well for the foresight of the British committee that the recommendations remained virtually unchanged by the revision made at the fifth International Congress, held in Chicago in 1937, but it is a poor reward for their labours that it should now be found necessary to publish the letter on page 175. There were not lacking signs even before the war that the medical conscience had gone to sleep again, a lapse due in part to the skill of the engineer in producing fool-proof apparatus. But even fool-proof machines are not meant to be used by fools. For example, the portable x-ray apparatus commonly supplied to E.M.S. hospitals gives an x-ray intensity of 165 r/min. at 15 cm. when running at 65 kV and 5 mA. so the radiologist gives instructions that the apparatus is not to be used without a 15-cm. cone. A surgeon in the theatre, however, asks the radiographer to remove the cone so that he can have the tube close underneath the patient; the intensity at 6 cm. distance is then 1,000 r/min., so that in one minute's screening he may not only burn the skin of the patient but almost sterilize his assistants as well. Because it is difficult for a radiographer working in the operating theatre not to obey the surgeon's orders, the responsibility of the surgeon for knowing what his order entails is all the greater. It is not impossible that some of the skin troubles put down to "plaster idiosyncrasy" are in fact due to excessive x-ray exposure, and for prolonged fluoroscopic work an accumulative timing device which turns off the apparatus when the total exposure reaches a certain previously determined limit is very desirable.

A related difficulty is occurring in radiotherapy, and is also probably due to the dispersal of hospital staffs over

the countryside. Postal directions for the use of radium or radon in a patient whom the sender has never seen are at their best unlikely to serve the true interests of the patient, and at their worst are improper. It would be idle to deny that some of these difficulties have their origin in a feeling that radiologists are trying to maintain a kind of vested interest; but "the first consideration is that the use of x rays and radium is dangerous both to the patient and to the doctor unless the latter thoroughly understands their use."

INHERITANCE OF HARELIP AND CLEFT PALATE

The problem of the inheritance of harelip and cleft palate is a difficult one, and no uncomplicated Mendelian scheme will fit the facts. Transmission is in general recessive, but the proportion of individuals affected is much less than the expected quarter. Furthermore, there is a sex difference, the condition being commoner in males than females. As in other similar instances, a two-gene hypothesis has been advanced: the combined action of an autosomal and a sex-linked gene, both recessive. Csik and Mather¹ have shown that the sex difference cannot be due to sex-linkage. It is fairly clear that only a proportion of the bearers of the abnormal gene show any malformation, and that, for some reason at present unknown, that proportion is higher in males. Mather and Philip, in an analysis in a recent paper,² use the methods associated with the names of Fisher and of Haldane, applying them to two large collections of data, those of Sanders and of Schröder. To add to the difficulty of analysis and interpretation Schröder's data were admittedly selected for high incidence. First of all it was found that the two sets of data differ. Sanders's data are homogeneous and indicate the presence of an autosomal recessive gene. Actually, it is possible that any one of several genes might be responsible; the methods used could not elucidate this point. Schröder's data are not homogeneous. While a proportion of cases is due to an ordinary recessive gene (or one of a number of such genes) others give clear evidence of partial sex-linkage. It is remarkable that almost simultaneously with Haldane's demonstration of partial sex-linkage in the transmission of spastic paraplegia³ another instance should have been discovered. (Briefly, partial sex-linkage means the transmission of a gene situated on the pairing portions of the X- and Y-chromosomes and showing a far more subtle relation to sex than ordinary, sex-linked, X-borne genes, such as that responsible for haemophilia.) Having established that at least two genes must be responsible in Schröder's cases, a re-examination of the descriptions of the cases revealed that the genetic difference did correspond to a clinical difference, though not an absolute one, for the partially sex-linked cases tended to be more severe. The authors of this paper have performed a service in showing that, provided the new methods are used, successful analyses can be made when the genetic situation is far from simple, and, furthermore, when the data are far from perfect. The devising of the new methods has been a triumph of statistical skill, though fortunately their use does not demand corresponding mathematical abilities. Further examples of the proper use of the Fisher methods will be very welcome, however, to those who are not mathematicians and are starting to use them with some natural timidity.

LIVER FUNCTION IN GRAVES'S DISEASE

It has been shown by Elmer and his co-workers¹ that the liver is the organ most concerned with the excretion and detoxication of thyroxine. Liver damage in hyperthyroidism might, therefore, be of great clinical interest, and there is now evidence that it often occurs. This evidence, which has been reviewed by Lichtman,² who also contributes new data on cincophen oxidation and galactose tolerance, is derived from three sources. The administration of thyroxine to animals produces functional and anatomical changes in the liver; necropsy material from thyrotoxic patients has disclosed a high proportion of abnormal livers; and liver-function tests have frequently given abnormal results. One of the few uncertain links in this chain concerns the possible role of increased intestinal absorption in those tests of hepatic function which depend upon the oral administration of the test substance, and we have already noted in these columns³ the divergent views of Althausen, Lockart, and Soley⁴ and of MacLagan and Rundle⁵ on the impaired galactose tolerance, which is evidently a characteristic finding. It appears that increased absorption occurs in thyroxinized rats and probably in thyrotoxic patients,⁶ but it has not been shown that such increased absorption would necessarily impair galactose tolerance by itself, for it has not been studied apart from thyroid intoxication. The question is difficult to investigate directly in the human being, but it is significant that many of the intravenous liver-function tests, which must be independent of the absorption factor, have given positive results. Thus, Youmans and Warfield⁷ found retention of phenoltetrachlorophthalein in the blood in twenty-two out of forty-eight cases, and Maddock, Collier, and Pederson⁸ retention of bromsulphalein in eight out of thirteen cases. There was a positive Takata-Ara reaction in six out of fourteen of Ragins's cases,⁹ while Haines, Magath, and Power¹⁰ obtained abnormal results with the intravenous hippuric acid test in four of the six cases in which the test was done. It is still possible that increased absorption is partly responsible for the results where oral methods are used; if so, these might well possess an advantage from the purely diagnostic point of view. At present there is no general agreement on the clinical value of these tests in Graves's disease. Several authors have been impressed with the diagnostic possibilities and with the likelihood of relation between liver damage and thyroid crisis.¹¹ The latter is, however, denied by others,¹² and further work will evidently be necessary.

ISINGLASS AS A TRANSFUSION FLUID

In order to restore and maintain the volume of circulating fluid a transfusion fluid must answer the following requirements: (1) The molecule of the dissolved substance must be of such a size that the fluid will not leave the vessels too freely. (2) The solution must exert an osmotic pressure and possess a viscosity approaching as closely as possible that of whole blood. (3) It should be as nearly as possible isotonic with the contents of the red cells. (4) It must be non-antigenic and innocuous. A 7% solution of ordinary gelatin made from animal sources¹³ in 0.9% saline is satisfactory except as regards the last point. Cases have been recorded in which gelatin has been responsible for infection

with anthrax or tetanus. Fish gelatin or isinglass should theoretically be free from such contaminations. N. B. Taylor and E. T. Waters¹⁴ have just published some interesting experimental observations on the use of special purified isinglass in dogs after severe haemorrhage. A 7% solution in 0.9% saline was employed. This was found not to gel at room temperature. When the blood pressure had fallen to a dangerously low level after bleeding the isinglass solution was transfused slowly (in from 15 to 20 minutes) into the femoral vein. In most of the experiments haematocrit determinations were made before and after bleeding in order to check the proportion of the blood volume which according to calculation had been lost, though the authors realize that such figures are not altogether reliable. In experiments in which large quantities of blood were rapidly removed it was found that transfusion with isinglass, even when incomplete replacement was affected, caused and maintained a satisfactory rise in blood pressure, though the animals subsequently died, probably from other contributory factors such as unsatisfactory anaesthesia. In a series of survival experiments in which an amount of blood was withdrawn which might be expected to cause death in an untreated animal, very good results were obtained with transfusions of isinglass. The animals made complete and uneventful recoveries. It was found that a mild degree of sensitization which lasted only two weeks followed the transfusion. It is hoped that further purification may prevent such sensitization from occurring. The fate of isinglass after its introduction into the body is now being investigated. The authors suggest that it is probably broken down and used by the tissues, and is therefore preferable to gum acacia, which the body is unable to metabolize as a transfusion fluid. The viscosity of isinglass is about double that of serum and plasma; this, it is suggested, is also an advantage. It would appear from these preliminary studies that if a really pure non-sensitizing isinglass can be prepared it will merit more extensive trial on human as well as on animal subjects.

VITAMIN B₆ (ADERMIN)

Rat acrodynia, caused by a deficiency of vitamin B₆ in the diet, is characterized by symmetrical dermatitis with oedema and scalliness, mainly on the peripheral parts of the body—e.g., mouth, nose, paws, ears, and tail. Chick *et al.*¹⁵ have distinguished three different types of skin lesions in rats cured respectively by riboflavin, filtrate fraction, and eluate fraction (containing vitamin B₆) from yeast extracts. During a deficiency of riboflavin, rats developed an eczematous condition of the skin, particularly of the nostrils and eyes. When deprived of the filtrate fraction, which contains pantothenic acid and probably other essentials also, the rats' coats were poor and matted and the pigmented areas over the heads and shoulders often became grey. The fur of the forearms and abdomen was frequently stained with a reddish exudate containing protoporphyrin. Rats deprived of the yeast eluate fraction (containing adermin) developed the characteristic dermatitis and, in time, a tendency to fits of an epileptic nature. These fits showed different stages—a sudden rushing about and leaping into the air, with the eyes protruding and sometimes suffused with blood; a helpless condition with muscular twitching of the limbs and tonic spasms; a comatose state with a slowed and weakened heart-beat and absence of corneal reflex; and gradual recovery, first of the head and fore-

¹ *Iodine Metabolism and Thyroid Function*. Oxford, 1938.² *Ann. intern. Med.*, 1941, 14, 1199.³ *British Medical Journal*, 1941, 1, 367.⁴ *Amer. J. med. Sci.*, 1940, 199, 342.⁵ *Quart. J. Med.*, 1940, 9, 215.⁶ *Arch. intern. Med.*, 1926, 37, 1.⁷ *West. J. Surg.*, 1936, 44, 513.⁸ *J. Lab. clin. Med.*, 1935, 20, 902.⁹ *Ann. intern. Med.*, 1941, 14, 1225.¹⁴ *Canad. med. Ass. paws and later of the hind legs. Pure vitamin B₁₂ cured these rats and also prevented the onset of the condition in the control animals. Schneider *et al.*⁴ have found that acrodynia may be cured by giving vitamin B₁₂ together with unsaturated fatty acids or the filtrate from rice bran extracts similar to the liver and yeast filtrate fractions. Apparently acrodynia in their rats was not the simple dermatitis due to a deficiency of vitamin B₁₂ only, but a more complicated one due to a deficiency of at least two factors. György and Eckardt⁵ distinguished three different kinds of cutaneous lesions in rats which were supplied with vitamin B₁₂, aneurin, and riboflavin, and they also concluded that the rat needs at least one other member of the vitamin B complex for perfect nutrition. The use of vitamin B₁₂ in human nutrition has recently been reported by Spies *et al.*⁶ who obtained dramatic relief of symptoms (extreme nervousness, insomnia, irritability, abdominal pain, weakness, and difficulty in walking) in patients who had been treated successfully for pellagra and beriberi but had remained on their deficient diets and retained the above symptoms. Antopol and Schotland⁷ obtained considerable improvement in the condition of 6 cases of pseudohypertrophic muscular dystrophy. It is, however, possible to give too much vitamin B₁₂. Unna⁸ has found that the L.D.₅₀ of vitamin B₁₂ hydrochloride for rats is 3.7 grammes per kilogramme following subcutaneous injection and 5.5 grammes per kilogramme following oral administration. Doses above 1 gramme per kilo produced toxic manifestations in dogs, rabbits, and rats, characterized by impairment of the co-ordination and tonic convulsions, but this dose was at least 1,000 times the therapeutic dose. The metabolism, circulatory and respiratory systems, and isolated smooth muscle organs of normal animals were not affected.

THE MENOPAUSE

Puberty and romance are not strangers. The young woman becomes conscious of new hopes and new powers which are undismayed by the occasional faint whisperings of a nameless fear. Autumn irrevocably follows summer, and so the years of full glandular activity and co-ordination lead at last to that stage of hormone readjustment which marks the critical period of "the change of life." Fears now predominate, for a while at least, though time often proves them ill founded when, instead of a dreaded disintegration, there is revealed that new physical and spiritual beauty which Whistler has immortalized in the portrait of his mother. From earliest times the menopause has been regarded as the critical stage in a woman's life, but it is surprising what confusion still exists in the minds of both laity and profession as to which symptoms are to be regarded as normal and which are warnings of impending or present dangers. There has been controversy for many years over the question whether an artificially induced causes more distress than a spontaneous menopause and whether symptoms are worse after irradiation or surgery. Hugh McLaren⁹ has published two interesting papers on this subject from the department of obstetrics and gynaecology of Aberdeen University. His first dealt with the normal and the second with the induced menopause. In the first group it was found that hot flushes occurred in approximately 50% of cases before the menopause, but less commonly afterwards. They did not usually cause incon-

venience, but the incidence of severe flushing was greater after than before. Post-menopausal atrophy of the genitalia was found to be by no means a constant feature, but when it did occur the vagina was involved at an earlier stage than the external genitalia. In over half the cases studied, however, there was little anatomical or physiological change. When the menopause was induced by irradiation or by removal of the ovaries it was found that hot flushes caused inconvenience in half the cases, being much more common than during a normal menopause. They seldom appeared, however, when a hysterectomy was performed with conservation of the ovaries. In view of the argument which has centred from time to time on this question of ovarian conservation these results are significant.

The analysis also revealed that atrophy of the vaginal mucosa was rare when ovarian tissue was conserved, but took place in 14% of cases of radiation menopause and in 28% when oophorectomy was performed with hysterectomy. A complication of radium therapy to which the author draws attention is the occurrence of vaginal strictures, which happened in 8% of his series. This figure excluded the many cases of stenosis of the vaginal fornices, which is common even after a normal menopause. The change thus induced in the anatomy and physiology of the vagina may have serious results in the domestic life of the patient, and the possibility of this should be remembered when the choice of treatment is being considered. Though there is much that commends radiation as a means of inducing the menopause, the superficial advantages must not be allowed to mask the real dangers. The greatest of these lies in the failure to select the suitable case carefully. In view of the possibility of overlooking an early carcinoma it can scarcely be over-emphasized that no woman should have a radiation menopause induced either by radium or by x rays before an exploratory curettage has been performed. It should also be remembered that excessive bleeding and intermenstrual bleeding are pathological, and without investigation should never be dismissed lightly as signs of "the change of life." The fact that such avoidable mistakes are still made is one reason why the menopause continues to be a critical period in the life of a woman.

THE HALF-YEARLY INDEXES

The usual half-yearly indexes to the *Journal* and to the *Supplement* will soon be ready. They will, however, not be issued with all copies of the *Journal*, but only to those readers who ask for them. Any member or subscriber who wishes to have one or both of the indexes can obtain what he wants, post free, by sending a postcard notifying his desire to the Accountant, British Medical Association House, Tavistock Square, W.C.1. Those wishing to receive the indexes regularly as published should intimate this.

In the *Supplement* this week (p. 15) we publish a letter which has been sent by the Secretary of the Central Medical War Committee to the Under-Secretary of State for War on the commissions now being granted to women doctors. At present women practitioners serving with the Army for the duration of the war are not officers of the R.A.M.C. In the opinion of the Central Medical War Committee they should be granted the same rank, status, and title as men, a women's branch of the R.A.M.C. being created if necessary. The present position constitutes a denial of an accepted principle of the medical profession, which recognizes no distinction between the sexes in the execution of professional duties.

SURGICAL PRINCIPLES IN DIVISIONAL MEDICAL UNITS

BY

Colonel C. MAX PAGE, D.S.O., M.S., F.R.C.S.

Surgeon to St. Thomas's Hospital; Consulting Surgeon, Eastern Command

The work of divisional medical units under conditions of active service is mainly aimed at the efficient evacuation of casualties. It has become clear in the present campaign that a smooth and rigid scheme of treatment and evacuation from aid posts to casualty clearing stations as was possible in 1917-18 cannot be achieved. The medical services in the field must adapt their activities to events, and though it is impossible to forecast the circumstances under which individual units will work, the general principles of wound-treatment should form the background of their action in relation to the individual wounded man. There is no doubt that the treatment he receives in the zone in question has a great influence on his subsequent condition, and an attempt will be made below to define what should or should not be done with a wounded man in regimental or field ambulance posts.

We started this war with a clear idea of the ideal wound treatment: this was founded on the experiences of 1914-18, and was to some degree coloured by reports on Spanish practice in their civil war. Since then experiences with our Expeditionary Forces and at home have done little to alter the established principles, though they have brought to light the value of the sulphonamide group of drugs in prophylaxis. Moreover, there has been activity on the research side both in relation to these drugs and into the value of antisera for anaerobic infections. The importance of fluid replacement in the treatment of shock has become fully recognized, and the provision of preserved blood or a substitute has been put on a sound basis.

Importance of Early Operation

Whatever adjuvants to wound treatment we may now possess nothing has lessened the proved importance of early operation for the majority of the wounded if serious infection is to be avoided. The operation in general will be one of débridement or the establishment of drainage, in accordance with the time-lag imposed and the surgical conveniences available. Primary repair is aimed at only for intra-abdominal injuries and those of the chest wall and skull. Primary suture of a somatic wound is not advisable except in very carefully selected cases. The ideal time for operation after the man has been injured cannot be defined with absolute precision. It is generally recognized that the period during which a radical excision or repair operation is likely to be satisfactory is within at most twenty-four hours of injury. Subject to the necessary period of resuscitation most authorities would reduce the ideal time-lag to twelve hours.

Our organization in the forward area is based, therefore, on getting the seriously wounded into the care of a surgical centre with the minimum of delay. The term "surgical centre" is used to imply any organization where formal surgery and the full process of resuscitation can be carried out. The difficulties in conforming to this ideal under the varying conditions of modern war are only too patent. We have to admit this handicap and aim at adaptability and elasticity in this matter as in other spheres of Army activity.

Treatment in Forward Units

The following may be laid down as the procedures to be carried out for the wounded at the aid post before transfer to the surgical centre:

1. A simple dressing of adequate size is applied to the wound if this has not already been done.

2. If the patient has not already received it, A.T.S. (3,000 units) should be given and the fact notified on his field medical card. The employment of anti-gas-gangrene

serum at this stage may be of value, but a decision as to its general use has not been arrived at. Sulphanilamide may be administered to the more seriously wounded, especially in cases in which fractures are present. It should be given by the mouth, a 2-gramme dose to start with and 1 gramme at four-hourly intervals subsequently up to a total of about 20 grammes. A note as to the time the treatment started and the dosage given should always be entered on the man's documents for future guidance. The question of packing the wound with sulphanilamide is referred to below.

3. *Shock.*—The first need of the wounded man is for rest, warmth, relief of pain, and drink. Simple though these demands are in quiet periods, in forward units they cannot always be completely satisfied under conditions of activity. When achieved they go far to bring a man out of primary shock. Transfusion of serum or plasma will of necessity be limited by the conditions of the aid post and other circumstances. In general, it may be said that the transfusion of a pint of serum or plasma at this stage should be reserved for serious fracture cases or for those in which a severe haemorrhage has been controlled by ligature. For a serious burn similar treatment will sometimes be advisable before evacuation, but it is evident that the storage of the necessary material and the conditions for the proper administration of a transfusion will exist only in the larger aid posts.

The following notes are concerned with the treatment of special conditions.

Fixation of Fractures

Satisfactory fixation of fractures before evacuation is of the first importance if secondary wound shock and increased local damage are to be avoided. For fractures of the thigh and in the region of the knee the Thomas splint is of the greatest value. It should be applied in accordance with the recognized method, over the clothes with the boot and sock still in place. Traction is exerted through a clip or skewer attached to the boot or by binding the foot to a foot-plate. Traction should not be severe, nor should it aim at a complete reduction of any overlap of the fragments which may be present. A splint with a large-sized ring must be used for these cases, and therefore the result of forced traction is to push the ring up into the femoral angle, producing a condition that is both uncomfortable for the patient and liable to produce a pressure sore. The tension applied should only be sufficient to stabilize the fragments. The ring of the Thomas splint, when too large, can be to some extent stabilized by packing between the upper part of the thigh and the outer section of the ring. Judicious suspension of the ring from a suspension bar attached to the stretcher will also have the same effect.

Fractures of the tibia and fibula may be treated in the same splint. As a rule little or no traction is required, but control of the rotation of the lower fragment should be obtained by binding the foot to the foot-piece. In fractures of the lower half of the leg a simple box splint with a foot-piece is, I think, preferable. This can be made from Cramer wire splinting or, if this is not available, from boards or Gooch splinting. A similar arrangement should be employed for the splintage of injuries about the ankle or foot.

In the upper extremity, fractures of the humerus in the proximal half of the bone, and including injuries to the scapula, are best fixed by binding the arm to the side with a pad placed between the arm and the chest wall; the forearm is supported by a sling. If the fracture is in the lower half of the bone or about the elbow-joint the use of a posterior splint extending from the shoulder to the hand is desirable, the elbow being set at about a right-angle. This splint is most conveniently made from Cramer wire splinting. If it happens to be available a plaster-of-Paris slat instead of the wire splint will serve even better, but there must be no question of applying a complete encircling plaster bandage in this phase. Fractures of the forearm, wrist, and hand should be immobilized on a section of Cramer wire splinting bent at a right-angle to hold the elbow. It should be noted that fixation of fractures in this

stage aims at immobilization rather than rectification of position. It will be sufficient if the limb is aligned in its splint in approximately the normal position. Tight bandaging, especially of the forearm and about the elbow, should be avoided.

Fractures of both lower and upper jaws can for the purposes of early transport usually be adequately fixed with the four-tailed bandage. If there is a tendency for the tongue to fall back owing to complete destruction of the symphysis, a stitch or two should be used for either fixation or traction. A feeding-cup with a rubber tube extension on the spout will facilitate feeding. If possible the man should be transported in the sitting position.

Spine.—It has become customary to advise the transport of spinal injuries in the prone position. This position is very uncomfortable and distressing for a stretcher journey of any length. Moreover, it renders access for catheterization impossible without considerable disturbance. The theory supporting this practice is that extension of the spine is thereby maintained, the position of extension preventing vertebral displacement and tending to reduce any deformity present. The prone position certainly has the advantage that it prevents the formation of dorsal pressure sores, though not those on the ventral aspect. It is clear that missile wounds of the spine, whether associated with cord symptoms or not, are not subject to this argument. The same may be said of impacted flexion fractures. It is doubtful if the position is of much importance in the case of fracture-dislocations provided that gross flexion of the spine is not allowed to occur. It is therefore advised that spinal injuries should be transported in the supine position. The man should be lifted by three persons, one of them taking care to support the spine at about the level of the injury in such a way as to prevent flexion. On the stretcher the lumbar curve is maintained by a small cushion or folded blanket. For cervical injuries extension is sufficiently maintained by a similar arrangement placed just above the shoulder level. In spinal injuries and wounds in which the cord or cauda has been involved the important point in early treatment is the avoidance of pressure sores and infection of the bladder. Pressure sores on the heels are less likely to form if sock and boot are left on, unless the latter are wet through. If available an air ring should be put under the buttocks. When retention of urine is present a gentle attempt at expression should be made; if this fails and the man is very uncomfortable catheterization may be carried out, but only if it can be done with aseptic precautions. If the case has to be retained for some days or if the period of transport is long, it will be well to tie the catheter in (Taylor, 1941).

Ribs.—If only a few ribs are broken the disturbance necessary for proper strapping should be avoided unless dyspnoea is extreme and the man is clearly unfit for transport. When many ribs are staved in it is best to strap the chest, completely encircling both sides. This fixation of the lower part of the chest will enforce diaphragmatic breathing, but it reduces the dyspnoea resulting from irregular chest movements.

Other Special Conditions

Amputations.—Primary amputation in the forward area should only be undertaken when the lesions of the soft parts are so gross or the damage to the main vessels is so complete that survival of the distal part is out of the question. If evacuation is good even when these conditions are present, operation should be deferred until the surgical centre is reached, so that a more formal procedure can be there carried out than is usually possible in an aid post. It is said that the development of secondary wound shock can be checked (M.R.C. War Memo. No. 1, 1940) in such cases by the application of a tourniquet immediately above the wound.

Chest Wounds.—Wounds in this area rarely require more than a surface dressing unless an open pneumothorax or sucking wound is present. In this latter event it is important to close the opening effectively. Suture with this in view should not be carried out unless complete wound

excision can be coupled with it. A large greased pad covered with mackintosh tissue should be strapped over the opening (Barrett, 1940). Elastoplast will be most satisfactory for the purpose, but ordinary adhesive tape will serve. The strapping should overlap and extend over the whole pad. Occasionally an early pressure pneumothorax may be met with. Cyanosis and dyspnoea, together with displacement of the apex beat and sometimes the trachea, will enable a diagnosis to be made (Sellors, 1941). When it is recognized it should be relieved by needle puncture at once.

Abdominal Wounds.—In the ordinary way the wounds will be protected and the patient marked for early evacuation to the surgical centre. Morphine should be given in those cases in which diagnosis of perforation of the gut is evident from the position of the wound or from the clinical signs. No attempt should be made to return prolapsed viscera or omentum; they should be covered with a normal saline pack or plain dressing and bandaged, a note being made of the state of affairs on the F.M.C.

Head Injuries.—A simple protective dressing only should be employed, even when there is prolapse of brain. A note as to the mental state of the patient and a record of the pulse and condition of the pupils or any paralysis which may be present should be made on the F.M.C.

Burns.—The treatment of burns in the initial phase is directed to preventing shock, which may prove fatal. If, however, the burn is of such a size as not to endanger life the main consideration is quick healing and the restoration of function. The danger to life from extensive burns is best treated by some method of surface coagulation. Tanning has proved the most satisfactory in this respect. The tanning is perhaps best effected with tannafax jelly or the application of compresses wrung out in 2% tannic acid. The latter method of application is most convenient in cases to be evacuated shortly. Smaller burns, and any burns of the face and hands, should not be tanned; they should be powdered with sulphanilamide and then covered with vaselined lint or gauze. No attempt at surgical cleansing is made. There are several pastes on trial for application under these conditions, but it cannot yet be said that any have proved their superiority to the simple method suggested (E.M.S. Memo., 1941).

Haemorrhage.—As a serious problem haemorrhage does not appear as often in aid posts as one would expect from a perusal of first-aid treatises. No doubt if a major vessel is torn open a man dies before aid can be given, and he does not reach the aid post. If a medium-sized vessel is divided completely it has considerable capacity of retraction, and in the condition of shock which is produced by the injury self-sealing will very likely occur. When bleeding is obviously continuing from a wound an attempt should be made at the dressing station to control the bleeding-point with a ligature or forceps. If a tourniquet has been applied it is most undesirable to continue its use for longer than is necessary. In a large proportion of cases in which a tourniquet has been applied in the field haemostasis would have occurred without its use, for it takes place after the tourniquet has been in position for half an hour or so. For haemorrhage from minor vessels firm pressure exerted by a pad bandaged in place, coupled with recumbency, will often suffice for control.

Priority in Evacuation.—When evacuation is normal and the journey to the surgical centre can be effected in about an hour abdominal injuries should have precedence. Fractures and sizable retained foreign bodies should come next, and chest and head injuries last. If the pressure of casualties is very great this order will clearly have to be altered, and the alteration must be determined by the medical officer on the spot, since he has a knowledge of the local conditions and surgical possibilities.

Isolation of an Aid Post.—When evacuation is impossible and an aid post is isolated and therefore saddled with the responsibility for the wounded over possibly a period of several days, it is clear that an attempt should be made to produce the conditions of a surgical centre. In fact this will not often be practicable on account of the lack of personnel and of the necessary amenities. Formal or radical operations for abdominal wounds will seldom be carried out,

and the same may be said for chest and head injuries. The surgical treatment of open fractures will be directed to effecting free drainage rather than radical wound excision. Amputations should be carried out for gangrene or for local infections which may threaten life.

Pansement d'Attente.—The main efforts of available personnel should be directed to the prophylactic use of sulphanilamide for all serious wounds—or, if circumstances permit, all wounds. This treatment should be made effective as soon as possible. From 5 to 20 grammes should be introduced into each wound, according to its size; a total of 40 grammes should not be exceeded in any individual. Enlargement of the wound may be necessary to give complete access. Foreign bodies which have been located and are easy to remove should be extracted at this stage. The powder should, so far as is possible, be brought into contact with the whole wound surface or track; it should not be tightly packed in. An insufflator, if available, may be used; but it would appear that introduction with a small spoon of known capacity is more convenient. If instead of powdered sulphanilamide the tablets are used, the latter should be crushed before introduction in order to facilitate absorption by the tissue fluids. The prophylactic use of the drug by mouth as detailed above should be reserved for cases in which the development of serious infection is deemed probable: missile fractures and irregular retained foreign bodies are instances which would come into this category.

Summary

The above is a brief outline of the surgical principles which should determine our treatment of the wounded man in the forward area, together with an attempt to summarize practice. In war any set plan can seldom be carried through in every detail. We should have a clear conception of the ideal at which we aim, and in action do our best to attain it despite unforeseen difficulties and inevitable handicaps.

I should like to acknowledge my indebtedness to Brigadiers F. Laing and E. M. Cowell and to Colonels J. Weddell and L. Colebrook for useful suggestions and advice in the preparation of this memorandum.

WORK OF THE LISTER INSTITUTE STUDIES OF VITAMINS IN WHEAT FLOUR

It is fifty years since the Lister Institute (then called the British Institute) of Preventive Medicine was incorporated, but as active work did not begin until 1893 any jubilee commemoration is postponed until the year after next, by which time it is hoped that the dawn of peace will be stimulating research in every field. Meanwhile the report of the Governing Body for 1941 contains an account of much interesting work. Probably the studies on accessory food factors claim the most immediate importance in view of the food situation in this country.

The Division of Nutrition, which is located at Cambridge, has been devoting its energies to filling the gaps in knowledge which still exist as to the nutritive value of different portions of the wheat grain. The flour generally used in this country for making white bread represents 73% of the wheat grain, the remainder being discarded and used for animal feeding. Wholemeal flour (100% extraction) has been shown to be richer in mineral constituents and to contain more vitamin B₁, more of the vitamin B₂ complex, and proteins of higher nutritive value than white bread. But some of the previous investigations are based on results which could be criticized in the light of more

modern methods, and therefore it was thought desirable to investigate further the digestibility of bread made from wholemeal and white flour respectively, the relative nutritive value of the proteins contained in each, and their content of the different members of the vitamin B₂ complex.

Superiority of Wholemeal

So far as digestibility is concerned, the observations were made on six volunteers who for ten or eleven days consumed diets consisting almost entirely of bread made from the different types of flour. In the white bread ingested, "5% of the energy" and 9% of the nitrogen was found in the faeces, the corresponding figures for the wholemeal bread being 13 and 14% respectively. It is calculated that in the manufacture of white flour about 20% of the total energy available to man in the wheat berry is discarded, while of the nitrogen 27% goes into the offals. None of the subjects was adversely affected by the wholemeal breads, of which they consumed 2 to 2½ lb. daily.

The nutritive value of the proteins of white and wholemeal flours was studied by comparing the growth of young litter-mate rats. After adjustments had been made to secure a fair comparison, the rats on wholemeal diets were found during the observation period of nine weeks to have a weight increase nearly twice that of rats on the white-flour diet. A 30% superiority in nutritive value for the proteins of the whole wheat was confirmed by other experiments. Similar experiments on rats were carried out to determine the value of B₂ vitamins in the flours. The diets were made equal in other respects, but the rats receiving the white-flour diet, even though fortified with vitamin B₂, showed a rate of growth which was only about one-half that of the group receiving the wholemeal. The superiority is attributed to the higher content of B₂ vitamins in the wholemeal as compared with the white flour.

Some work has been done on the fat-soluble vitamins in wheat flour. In the process of milling a considerable part of the fat contained in the germ of the wheat grain is disseminated throughout the flour. The fat-soluble vitamins present in this oil are provitamin A (carotenoids) and vitamin E. The biologically active fraction of provitamin A is very small, so small that rats living on a diet composed almost entirely of flour failed to obtain sufficient to protect them from vitamin-A deficiency. Wholemeal flour is no richer than white flour in this respect. The bleaching of flour to get rid of its creamy colour destroys the carotenoid pigments, but the amount is so small that it cannot be regarded as a serious nutritive loss; the possible damage to other nutrients, especially vitamin E, is under investigation.

Yeast as a Human Food

The nutritive value of yeast, with its high content of B vitamins, has been studied, more particularly the supplementary value of the B vitamins of the type of yeast known as *Torula utilis* to those in straight-run white flour. The addition of 2½% yeast to white flour makes it as good a source of B vitamins as wholemeal flour, and the addition of 5% makes it a better source. This amount of yeast may be added to white or wholemeal breads without seriously affecting their palatability, and in soups, meat and vegetable stews, and many other dishes yeast may be added in reasonable amounts with advantage. Work done on vitamin C showed that tomatoes grown in the open had markedly more antiscorbutic potency than those grown under glass. Some biological tests have been carried out on strawberries, the jam of which is popular and can be made available at times of the year when natural vitamin C is not so plentiful as at others. The antiscorbutic potency has been found to be of the same order as that of citrus fruits.

Serological and Biochemical Studies

Only the briefest reference can be made to much other research work. An inquiry has been held into the toxicity for mice of *Cl. welchii* strains from war wounds and air-raid casualties. While there is little doubt that the more toxic strains are likely to exert a more harmful effect upon the resistance of the patient than the less toxic, it is equally clear that even the least toxic are capable of setting up gas gangrene. The main source of danger lies in the conditions obtaining in the wound.

Experiments have been continued on antityphoid vaccination, especially with a view to preserving the Vi antigen. It has now been found that a vaccine that is not only killed with alcohol but preserved in it still contains the Vi antigen in its effective form after storage in the cold for at least nine months, and probably much longer.

In some work on the antigenic complex of *Bact. dysenteriae* (Shiga) it has been shown that agar, which by itself is non-antigenic, can be rendered antigenic by combination with the polypeptide components isolated from the antigen of this organism or the O form of *Bact. typhosum*.

The study of the manifold effects of sex hormones has been proceeding. One point investigated is whether oestrogenic hormones are necessary in the male organism for the normal development of the sex organs. In the male organism such large quantities of this female hormone are produced that some consider that for the commercial manufacture of oestrone the urine of the stallion is a better source than that of the mare. Therapeutic treatment with oestrogens of male patients suffering from prostatic hypertrophy has been advocated. The Lister Institute workers, however, find that when administered simultaneously with male hormones, oestrogens produce a very small increase in the development of the sex organs as compared with that which can be produced by increasing the dose of male hormone alone. It is concluded that the female hormone is not only unnecessary for the normal development of the sex organs in the male organism but may be harmful in view of the pathological (including precancerous) changes which oestrogens produce, and in any case its therapeutic application in the treatment of diseases of the male sex organs is not warranted.

To the National Collection of Type Cultures of Micro-organisms, which is housed at Elstree, 150 strains, many representing new types, have been added during the year.

MINISTRY OF HEALTH STAFF

The following appointments and promotions in the medical staff of the Ministry of Health have recently been made by the Minister of Health:

Senior Medical Officers: E. L. Sturdee, O.B.E., M.R.C.S. (in charge of the Regional Medical Organization, including environmental hygiene; succeeded Dr. H. A. Macewen, O.B.E., who has retired from the service of the Ministry). W. A. Lethem, M.C., M.D. (Food and Nutrition).

Principal Regional Medical Officer of the London Region: M. D. Mackenzie, M.D.

Deputy Senior Medical Officers: N. M. Goodman, M.D., C. J. Donelan, M.B., Miss G. I. Brodie, M.B., V. D. Allison, M.D.

Regional Medical Officers: G. V. Davies, F.R.C.S., D. L. MacKenna, M.B., W. G. McKenzie, M.C., M.R.C.S.

The German journal *Archiv für Schiffs- und Tropen-hygiene* has with the new year changed its name to *Deutsche Tropen-medizinische Zeitschrift*, and will in future appear fortnightly instead of monthly.

BEIT MEMORIAL FELLOWSHIPS

A meeting of the trustees of the Beit Memorial Fellowships for Medical Research was held on July 23. It was noted that out of the thirty present Fellows thirteen had already been seconded at their own request for more direct service during the war, and six others have undertaken some research work for Government Departments on problems arising out of the war.

Election of New Fellows

The following elections were made, all with permission for each Fellow to be seconded at any time for war duties:

Senior Fellowship (£700 a year).—T. R. R. Mann, M.D.Lwov, Ph.D.Camb. To continue his work on intracellular metallo-protein compounds, especially of red blood cells, at the Molteno Institute of Biology, Cambridge University.

Fourth-year Fellowships (£500 a year).—J. F. Danielli, B.Sc., Ph.D.Lond. To continue his work on the permeability of muscle fibres and of capillaries, at the Biochemical Laboratory, Cambridge University. Miss C. O. Hebb, M.A.Dalhousie, Ph.D.McGill. To continue her studies of physiological problems in relation to high altitudes, at the department of physiology, Edinburgh University. H. Lehmann, M.D.Basle, Ph.D.Camb. To continue his work on the influence of shock and of the suprarenal glands on glycogen synthesis, at the Biochemical Laboratory, Cambridge University.

Junior Fellowships (normal value £300 a year).—E. F. Gale, B.Sc.Lond., Ph.D.Camb., Fellow of St. John's College, Cambridge. To study bacterial amine production as a cause of non-specific infantile diarrhoea, at the Biochemical Laboratory, Cambridge University. W. Holmes, B.A.Oxf., Senior Demy of Magdalen College. To study the regeneration of nerve fibres after injury, at the department of zoology, Oxford University. Miss M. F. Lockett, M.D.Lond., M.R.C.P. To identify renal pressor substances responsible for experimental high blood pressure, at the Pharmacological Laboratory, Cambridge University.

Reports of Societies

YELLOW FEVER IN AFRICA

At the annual general meeting of the Royal Society of Tropical Medicine and Hygiene, with the president, Sir RICKARD CHRISTOPHERS, F.R.S., in the chair, a paper was read by Dr. G. M. FINDLAY on the present position of yellow fever in Africa.

Dr. Findlay said that recent events had clearly demonstrated the specificity of the mouse-protection test for immunity to yellow fever in the blood of human beings, and had shown that the area which had been marked out by this test as the endemic zone in Africa coincided very closely with the actual distribution of yellow-fever cases. The endemic zone now extended from the west coast of Africa just to the north of Cape Verde, along the southern border of the Sahara to the Anglo-Egyptian Sudan, and thence, bending southwards, it crossed the White Nile and extended as far east as, and quite possibly beyond, the Sudan-Abyssinian border; the eastern border of the area extended southwards through the western part of Uganda, and thence diagonally across the Belgian Congo to the mouth of the Congo River. Any area in this zone was liable to be the site of an explosive outbreak of yellow fever.

Three epidemiological types of yellow fever could be recognized in Africa—urban epidemicity, rural epidemicity, and rural endemicity. The first type was carried on by *Aedes aegypti* and was apparently due to the importation of yellow fever from the country into the town; in the second type it was impossible to exclude *A. aegypti* as a vector, as this mosquito was so widely distributed throughout rural Africa. The factors favouring rural endemicity were as yet unknown. It seemed most unlikely that infection could be maintained solely by the man-mosquito cycle. Although 20% of wild monkeys in the endemic zone were known to contain immune bodies in their blood, it was not considered likely that monkeys were sufficiently numerous to carry on infection in the absence of man. The possibility of other alternative hosts must therefore be considered. So far no wild animals other than one ostrich had been found to possess immune bodies in their blood, although in Columbia marsupials and certain other wild animals had been found to possess an acquired immunity. The sera of

numerous domestic animals in Africa—cows, sheep and goats, horses, pigs, dogs, and a camel—have been found to contain virucidal bodies against yellow-fever virus. The specificity of the mouse-protection test as applied to animals required further investigation, but the results so far obtained were suggestive. The possibility of a reservoir other than the mosquito but with a longer life could not altogether be excluded. The two chief problems in relation to yellow fever in Africa were the more efficient control of yellow fever in the endemic zone and the prevention of the spread to East and South Africa, with further extension to India and the Far East. Infection could be carried either by the infected mosquito or by the infected human host. Owing to the greater rapidity and the greater volume of traffic there was now much more chance of the virus spreading from the present endemic area and being carried either by plane, motor car, ship, or train to non-endemic areas. If infection reached East Africa there was at present a considerable chance of its passing across to Southern Arabia and India, because the dhows traffic was a replica of the shipping which during the seventeenth and eighteenth centuries carried yellow fever between Africa and America.

The methods of preventing the extension of yellow fever comprised more concentrated attacks on the breeding of mosquitos and more efficient control of aerodromes and of persons travelling by car from endemic to non-endemic zones. In immunization was to be found a most efficient means of prevention, and it was quite time that regulations were promulgated to forbid the residence in any yellow-fever area of any non-African who had not been immunized against the disease. In certain selected areas mass immunization of the whole population must be considered. At present the greatest difficulty in the efficient control of yellow fever lay in the multiplicity of authorities, each of whom was concerned solely with the condition of affairs within his own borders. Until there was a greater correlation of administrative effort yellow fever would continue to be a menace to the health of Africa and of the whole tropical world.

General Discussion

Dr. HUGH SMITH (International Health Division of the Rockefeller Foundation), who had recently been in charge of yellow-fever investigations in Colombia, gave a brief account of the present position in South America. In the past three years there had been no instance of an *Aedes aegypti*-transmitted outbreak, although there had been many outbreaks of jungle yellow fever. In Colombia yellow fever recurred again and again at intervals of one or more years in the same isolated valleys, often within a short distance of a previous outbreak. Intensive studies had been made of all outbreaks, and so far no other arthropod than mosquitos had been found infected. On eight occasions, however, virus had been isolated from wild *Haemagogus* mosquitos. It was very difficult to account for the continuance of yellow fever in these areas, some of which were practically uninhabited. A high percentage of monkey blood, however, was positive for yellow fever, thus strongly supporting the suggestion that yellow fever could maintain itself in the absence of man. Although yellow-fever virus did not pass from one generation of *Aedes aegypti* to another through the egg, it was possible that this might happen with other mosquito vectors, and this question was now being investigated. The absolute impossibility of diagnosing yellow fever on clinical grounds was stressed. In eradicating yellow fever it was essential to combine immunization with eradication of *Aedes aegypti*; it was not, however, always easy to immunize a high percentage of the population. Efforts were now to be undertaken to eradicate *Aedes aegypti* from the whole of the Amazon Valley.

Colonel F. P. MACKIE drew attention to the difficulties imposed on air travellers by the differing regulations in force in different countries. Some countries accepted a certificate of non-exposure for six days; others insisted that if a person had been immunized against yellow fever he could not be admitted for ten days, while others extended the period to twenty-one or twenty-three days. Colonel T. MENZIES asked if combined vaccination against small-pox and yellow fever was recommended. It had been practised in certain French colonies. Dr. H. S. STANNUS said that he had never seen a case of blackwater fever in an

African, although such cases had been recorded. He suggested that they might in reality have been cases of yellow fever. Prof. T. F. HEWER drew attention to the difficulty in diagnosing cases of acute and subacute liver necrosis from yellow fever. Such cases, which were not uncommon, might in Africa be associated with black vomit. Brigadier RICHARDSON asked if there was any truth in the suggestion that dengue immunized against yellow fever.

Dr. FINDLAY, in reply, said it was now generally agreed that persons who had been inoculated against yellow fever were immune to the bite of an infected mosquito ten days later. There was absolutely no scientific justification for imposing quarantine periods of twenty-one days or over. Dr. HUGH SMITH concurred in these statements. It was impossible for anyone who had lived in an endemic zone to say that they had not been exposed to yellow fever, and certificates of "non-exposure" granted by any country in the endemic zone were therefore farcical. So long as immune bodies could be shown to be present in the blood by the mouse-protection test there was no need for re-immunization. If it was impossible to have a mouse-protection test carried out it was advisable to be re-inoculated every two years, although there was considerable evidence to show that anyone who had ever had immune bodies in his blood was immune for a considerable number of years. Combined inoculation by scarification of vaccinia and yellow fever was not favoured. Dengue and yellow fever gave no cross-immunity.

NASOPHARYNGEAL DISEASE IN MENTAL DISORDER

At the one hundredth annual meeting of the Royal Medico-Psychological Association, held in London on July 17, a discussion took place on diseases of the ear, nose, and throat in mental disorder.

Dr. T. G. GRAVES, president of the Association, said that the region of the ear, nose, and throat was a part of the body where there was the greatest concentration of functionally differing nerves and end-organs and other essential lines of communication, and this area also, from the point of view of absorption, formed the beginning of the visceral sheath. Here, therefore, disease, effecting positive and negative disturbances of sensation, could in the mind confused by toxæmia emanating from the same source produce an erroneous conception of environment. He added that clinicians who professed interest in the chronic infective process seemed to regard its importance very differently. For example, quite recently two important but separate clinical reviews had covered the subject with the sentence, "Of course, obvious septic foci should be removed." The adjective "obvious" seemed a meaningless and therefore unnecessary qualification.

Mr. H. G. BEDFORD RUSSELL said that it was often forgotten that the earlier response on the part of the tissues to infection with streptococci was the production of oedema, not pus. The presence of pus might be misleading in the establishment of the diagnosis of sinusitis. The phenomenal power of swelling possessed by the sinus lining resulted in localized pains in various parts of the head. The generalized headache might be understood when it was recalled that the trigeminal nerve supplied the meningeal as well as the nasal sinuses. There was considerable evidence that migraine was associated with an urticaria of the sphenoidal lining rather than inflammation thereof. He described a number of cases in which nervous disorder had been associated with unsuspected nose trouble, with oedema of the sinuses. There was a flavour of mental disorder about the symptoms of many patients who consulted rhinologists—he believed that this was more marked than among the patients who consulted gynaecologists. A typical trouble among these patients was carcinophobia.

Septic Absorption from Sinuses

Mr. ERIC WATSON-WILLIAMS said that the nasal accessory sinuses were, more often than the ear, the source of chronic septic absorption which caused trouble regarded as neurotic. Of the last 200 private patients seen by him who proved to be suffering from nasal sinusitis 87 complained of what might be

called a "toxic neurosis." Chronic toxic absorption produced a very definite effect on the mentality, often perhaps mild, but not seldom profound, and sometimes going beyond the borders of what a fairly tolerant public considered sanity. In the watch for focal infection it was not enough to pay regard only to the obvious sources, the teeth and tonsils; the ear should not be ignored, and a complete investigation should be made of the nasal accessory sinuses.

Mr. J. C. HOGG said that it must not be supposed that the rhinologist was often confronted with an obviously psychotic patient, but one could not help wondering how much incipient mild mental disorder was overlooked in a busy clinic. It was easy to take the view that sinusitis was due to pus, and that if there was no obvious pus there could not be sinusitis; but rhinology did not lend itself readily to over-simplification. Very slight pathological changes in the membranes lining the nasal sinuses would often give rise to severe and crippling headache; on the other hand, there might be widespread disorganization of the nasal sinuses without any pain whatsoever. Mr. R. S. STRANG said that he was quite convinced from the results he had seen that considerable amelioration or even cure of mental states could be obtained by the removal of chronic infective conditions of the ear, nose, and throat, even when such conditions were not obvious. He regarded a complete investigation of this region in mental patients as offering some hope of improvement. Mr. S. E. BIRDSALL said that the rhinologist saw a large number of cases of sinusitis, but in only a few of them could mental disorder be said to exist. Out of 80 such cases at a children's hospital, only 5 had been referred on account of what could be described as mental symptoms, such as listlessness, inattention, and excessive fatigue. School medical officers in their reference of cases evidently had in mind a connexion between being a dunce and having large tonsils, but in very many cases he thought it could be shown that the sinuses and not the tonsils were at fault. With regard to the ear, he believed that among deaf-mutes mental depression was uncommon; the deaf-mutes whom he happened to know were exceptionally happy and lively people. But it was very different with the person with acquired deafness of high degree (leaving on one side senile deafness), who was usually introspective, morose, depressed, and ill adjusted.

Dr. F. A. PICKWORTH, who gave a lantern-slide demonstration of pathological conditions, said that infection of the sphenoidal sinuses was not *per se* a cause of mental disorder, but was a source of vascular changes in the brain. He believed that such vascular changes inhibited neuron integration by obstruction at various synapses, so that the pattern of motor behaviour was rendered abnormal, and that clinical mental disorder became evident when such vascular changes were extensive or had a certain anatomical localization. Dr. H. F. FENTON said that as the superintendent of a mental hospital he had formed the firm opinion that cases of toxic infection did occur among mental patients, and that chronic as well as acute cases could be successfully treated. When focal sepsis was found and eradicated mental and physical improvement ensued in the majority of cases; in many the response was remarkable, and in those in which recovery did not occur there was generally a reduction in psychomotor activity, better behaviour, and improved health. Dr. ARTHUR POOL asked why, although practically the whole population suffered from colds, only a small percentage developed sinusitis. He suggested that a good many patients got and maintained their infection because they had not the right diet which enabled them to withstand the infective process. Before any patient was subjected to the severe operations which had been outlined he should be given the benefit of medical treatment, with the administration of adequate quantities of vitamin C, together with a regulation of the salt content of the diet. Dr. W. J. T. KIMBER wondered whether the change in the atmosphere and spirit of a mental hospital in which these methods of investigation and treatment were introduced might not have a psychological effect which in part explained the results. The more hopeful treatment of patients was in itself a valuable factor.

Dr. ASTLEY COOPER referred to some statistics circulated by the president, from which it appeared that out of a total of 3,050 patients, nasopharyngeal sepsis had been found in 2,754 (over 90%). This meant either that it was a universal cause

of mental disease and that its eradication ought to produce recovery or that the very universality of the condition made it negligible as a cause. "Improvement" appeared to be as inevitable as in all the recently introduced "successful" treatments of schizophrenia.

Dr. A. A. W. PETRE (president-elect of the Association) said that he was not entirely convinced that ear, nose, and throat trouble was the most important cause of mental disorder, but he shared with other medical superintendents the view that intensive investigation of patients for signs of focal sepsis was entirely to the good.

Local News

ENGLAND AND WALES

Mental Welfare

In the early part of 1939 the Mental Health Emergency Committee was constituted to function, in the event of war, in order to prevent the overlapping of mental health services. It included representatives of the Central Association for Mental Welfare, the Child Guidance Council, and the National Council for Mental Hygiene; later on representatives of other bodies were added. In its first report, covering a period of two and a quarter years, it describes the assistance its mental health workers have been able to render in reception areas among children who have been evacuated. The value of such work in its experimental stage was brought home to the Ministry of Health, which agreed to recognize the payment of these workers as an evacuation expense. A survey was made of the hostels for difficult children, and, with the beginning of intensive raids, help was given in the shelters and rest centres, as well as in the receiving areas in which the homeless people, especially those suffering mentally or nervously from the result of raids, were subsequently billeted. The Central Association for Mental Welfare, which also issues its report for two years, has to confess to some enforced suspension of activity, but it has been in a position to institute lectures on psychology to teachers, to arrange a course for medical practitioners, to help in arranging special billets for mentally unstable, subnormal, or senile individuals whose condition has been rendered more acute through shock, fear, or the destruction of their homes, to continue the visitation of epileptics in London and the Home Counties, and to carry out much other useful work. It is regretted that the report of the Feversham Committee on voluntary mental health services should have had to be shelved, but it is felt that the co-operation which has come about between mental health bodies as a result of the war has vindicated the recommendations of the report to a degree which would have been impossible to attain by ordinary propaganda alone. When the pages of the Feversham report are reopened and their contents publicly discussed "the discussion will be carried on in the light of incontrovertible practical experience, and the battle—if battle there be—will have been half won at the outset."

Appeal for London Hospitals

An appeal for £125,000 a year for hospitals during present circumstances was made at the annual meeting at the House of Lords of the King Edward's Hospital Fund for London, at which the President, H.R.H. the Duke of Kent, took the chair. The Duke of Kent said that uppermost in everyone's minds to-day, when they thought of hospitals, was the large number which had been bombed, and the endurance and bravery shown by the staffs as well as by the patients. The number of hospitals in the Metropolitan area, in which the Fund made its distribution of donations, which had been severely damaged now totalled 43, while a further 30 had been less seriously damaged in air raids. The Duke continued: "From what I have seen myself of hospitals in London and elsewhere, I can endorse all that has been said about what they have suffered and the way they have stood up to it. We are all specially grateful for the practical expression of sympathy which has come from our friends in the United States. . . . Our annual report refers to the schemes of some of the hospitals for moving part of their civil work to the country.

The King's Fund is watching this experiment with sympathy and interest, particularly because of the financial liabilities implicit therein. The King's Fund has already given additional help to the hospitals in the difficulties caused by the war and the conditions preceding the war. The annual distributions, both for 1939 and for 1940, were maintained at £300,000. Emergency grants totalling £80,500 were also made to a few hospitals during these two years. The combined result was that the total of grants and special administrative services was £307,000 in 1939 and no less than £384,000 in 1940." Reference was made to the work of the Voluntary Hospitals Parliamentary Committee, which included members of the King's Fund, the Nuffield Trust, and the British Hospitals Association, in presenting the case of the voluntary hospitals in connexion with Workmen's Compensation, the Purchase Tax, and the War Damage Act.

Hospital Contributory Schemes

Steps to increase and co-ordinate hospital contributory schemes are to be taken by a new representative committee set up by the King Edward's Hospital Fund for London. Contributory schemes have grown rapidly during recent years until they now provide an important part of the income of voluntary hospitals. Sir Kenneth Wigram, who is also connected with the Nuffield Hospital Trust, is the chairman of the new Contributory Schemes Committee, which includes representatives from the Voluntary Hospitals Committee, the Hospitals Savings Association, and the Hospital Saturday Fund. The Committee will examine the different schemes in the metropolitan area, making recommendations, and will also deal with the relation of London hospitals to schemes in the Provinces. The secretary is Mr. T. W. Place, for some years secretary of the British Hospitals Contributory Schemes Association.

Birmingham Accident Hospital

Since April last the Queen's Hospital, Birmingham, has become the Birmingham Accident Hospital and Rehabilitation Centre. Certain of the medical, nursing, and administrative staff have been taken over, as well as the buildings and equipment, and thus a specialized hospital has been established devoted entirely to the treatment and rehabilitation of men and women injured as a result of accident. The Board of Management has appointed Mr. William Gissane, F.R.C.S., of St. James Hospital, Balham, to be clinical director, and he is expected to take up his duties early in September. He will be assisted by a full-time staff with specialized knowledge, and a number of consultants will be associated with the work. The operating theatres, plaster rooms, and x-ray services will be available at all hours. There are 280 beds, certain of which will be set aside for observation cases in order that patients suffering from wounds may have a short period of in-patient treatment to ensure that complications will not develop. Rehabilitation by remedial exercises and occupational therapy will be carried out in a department to be set up for the purpose. Schemes have been prepared by the Board for the establishment at this hospital of schools for the training of nurses in industrial nursing and of selected personnel for industry and industrial first aid. The provision of a mobile surgical unit is also part of the Board's policy.

Merseyside Hospitals Council

The report of the Merseyside Hospitals Council for 1940 states that the income last year soared to a new high record of £280,284. The employers subscribed £46,220. In the three years immediately before the war the amount which it was possible to pay to the voluntary hospitals had each year fallen short by an average of £47,500 of the actual cost of the hospitals' services to members and their dependants—a sum very like that by which the hospitals collectively failed to balance their budget each year. This amount was made up during 1940 partly as a result of a plan known as the extra penny—whereby members subscribe not only a penny a week for every £ but for every part of a £—and partly because of the sharp upward curve in employment. Last year the associated voluntary hospitals received £113,246, which was £2,138 more than was distributed to them in 1939, leaving a balance of £47,000 from the year's revenue, which was held back for very good reasons. Some of the hospitals have moved to new quarters, others have suffered in air raids, and in the closing months of the year their many and varied needs were not

clearly known. Therefore the Distribution Committee, after discussing the financial position in all its aspects, decided to suspend the distribution of this reserve at least until the hospitals' financial position was known as at the end of the year 1940. Other items in the distribution were £33,104 for treatment in municipal hospitals, £14,667 to voluntary medical institutions other than the associated hospitals, £10,604 to civic war charities, and £9,400 to the medical staffs' fund. The offices of the Council have been moved to 40, Upper Parliament Street, Liverpool, their former headquarters having suffered air-raid damage.

SCOTLAND

Orthopaedic Progress in Scotland

At the annual meeting of the Princess Margaret Rose Hospital for Crippled Children, held recently in Edinburgh, Mr. W. A. Cochrane, the surgeon in charge, speaking of the success of treatment, said that many instances of notable achievements could be supplied. Sufferers from infantile paralysis had been cured, and in a number of very severe cases had been enabled to walk and lead an independent life. Deformed feet had been reconstructed and shortened legs restored to normal length. Upwards of 75% of the crippling conditions of childhood could be cured sufficiently for the child to grow up in a position which enabled him to earn his living on more or less equal terms with normal people. Besides carrying out its main purposes, the Princess Margaret Rose Hospital had been extended to provide for orthopaedic war casualties in the civilian population and in the Forces. Dr. Andrew L. Davidson, Chief Medical Officer of the Department of Health for Scotland, paid tribute to the hospital for its pioneer work in orthopaedics and its efficient organization. The care of the cripple, he said, was not only a medical but a social problem. The ideal to be aimed at was the prevention of crippling. Hitherto welfare work for cripples in Scotland had been backward and limited in scope, but even in these difficult times steps were being taken to establish regional orthopaedic schemes to cover the whole country.

An Edinburgh Nutrition Inquiry

The Edinburgh branch of the Children's Nutrition Council recently sponsored an inquiry into the adequacy of incomes and expenditures of 103 families with slender means, and has now issued a report entitled "Food and the War." The B.M.A. minimum diet, as laid down in the 1933 report of the Committee on Nutrition, was used as a basis for the inquiry, the items of food being repriced at their cost in Edinburgh in November, 1940. The income level of the families investigated was that of the unskilled labourer. The report states that the cost for an adult-man had risen since 1933 from 5s. 11d. to 12s. 6d., the rise for children was rather less, but on the whole food prices for a family were about doubled. Out of 76 families whose food bills were examined, only eight are regarded as spending enough to buy a diet adequate in every respect. The main cause of the inadequacy was lack of means; other factors were imperfect catering or inability to obtain a sufficient variety of food-stuffs. In achieving even the low nutritional standards brought to light, half of the families were over-spending their income and running bills from week to week with shopkeepers. The children, according to this report, suffer from lack of essential protective foods and may show the stigmata of stunted growth, deficiency diseases, and an inability to withstand the ravages of infections. While much could be done by furthering the knowledge of correct eating and the best possible use of available food in the homes, the main task is to ensure that enough food of the right kind is obtainable by all. Four measures are advocated: a wide development of communal feeding, expansion of all social services relating to food, extension of the National Milk Scheme to include children up to the age of 16 at least, and distribution of certain vitamins as a social service. Greater use should be made of Scotland's agricultural potentialities. A more equitable distribution of available foods is called for, and steps should be taken to ensure that wages, allowances, and old age pensions keep pace with rising costs of living. Copies of the report may be had from the Secretary, Children's Nutritional Council, 37, Esslemont Road, Edinburgh, 9 (price 3d., by post 4½d.).

Correspondence

Radiodermatitis

SIR.—There is good reason to believe that the risk involved in setting fractures or removing opaque foreign bodies under the fluorescent screen is not generally appreciated, and as the practice appears to be on the increase the Council of the Faculty of Radiologists desires to draw attention to this risk.

That the risk is a real one is shown by reports of cases of x-ray dermatitis of the hands and faces of surgeons in the E.M.S. in this country. There is also a report from Leddy and Rigos from the Mayo Clinic (*Amer. J. Roentgen.*, May, 1941, p. 696). They record fifty-five cases of x-ray and radium dermatitis in doctors in the period 1919-34 and eighty from 1934-9. Of the latter group only five were radiologists and the remainder physicians and surgeons. Of these eighty cases fifteen were the result of x-ray therapy and the balance occupational—that is, resulting from diagnostic procedures or handling radium. Forty-six cases (only three being radiologists) were directly due to manipulations under the screen—either setting of fractures or removal of foreign bodies. In thirty cases the injuries to the hands have gone the length of ulceration, twenty-one of the ulcers being malignant.

As no screen apparatus in use at present, not even the recent model using indirect vision, can protect the hands against the rays if the fractured limb is being manipulated or the foreign body being removed while the current is on, these two procedures should be actively discouraged. In both, the operator's hands are inevitably exposed to the direct beam of the rays. The Council of the Faculty is of opinion that these methods should be used only in very exceptionally difficult cases, and that, when used, the manipulation and viewing with the current on should alternate so that the hands are never in the direct beam. The Council also recommends that a radiologist well versed in the factors involved should be in attendance when these methods are used. Further safeguards are the use of an adequate filter, small milliamperage, and low kilovoltage—for example, 2 mA at 55 kV peak. Experiments show that the output is very greatly reduced if these factors are adopted.—I am, etc.,

M. H. CUPE,

London, W., July 24. Honorary Secretary, the Faculty of Radiologists.

Cardiac Arrest during Anaesthesia

SIR.—Mr. Hamilton Bailey's admission (July 19, p. 84) that he has performed cardiac massage on forty patients whose hearts "suddenly and unexpectedly became still during general anaesthesia" provides a terrible indictment of his anaesthetic service. Such a host of catastrophes could only result from grossly incompetent anaesthetists or, and far more probably, from the widespread use of chloroform.

Prevention is surely better than cure, especially since the cure was successful in only 10% of the cases. With all deference, may I suggest that Mr. Hamilton Bailey would do his patients a greater service by forbidding the use of chloroform in his theatres, except when it is specially indicated, than by drawing up rules of procedure to be adopted when the use of this drug has already caused complete cardiac arrest.—I am, etc.,

Manchester, July 19.

H. J. BRENNAN.

SIR.—Mr. Hamilton Bailey states (July 19, p. 84) that he has performed cardiac massage about forty times; only four patients have survived. One would be interested to know what type of general anaesthetic was administered, and particularly whether chloroform was used in any, or many, of these cases.—I am, etc.,

Durdee, July 19.

F. R. BROWN.

SIR.—Referring to the subject, "False Anaesthesia in Childhood," to be discussed by a body of anaesthetists, the late J. H. Nicol said he would prefer to entitle it "Anaesthetists' Incompetence." I was reminded of that remark by the very frank paper by Mr. Hamilton Bailey on cardiac massage for impending death under anaesthesia, and was surprised that, in times when the administration of anaesthetics has passed almost

entirely in hospital and nursing-home practice to the specialist, he should have found it necessary to perform cardiac massage "about forty times." If such an extreme procedure for resuscitation were so often necessary, how many times more must Mr. Bailey's work have been interrupted by the need for measures short of cardiac massage! That raises in my mind the question, "Has the competence of the anaesthetist kept pace with the increasing bulk of his plated paraphernalia?"

To one having come from a chloroform school, where, in the present view, mishaps would be expected to have been more numerous than to-day, it is astonishing that in these days of specialist administration any surgeon should be so unfortunate as to be called on to perform cardiac massage so often. Has Mr. Bailey been unfortunate in his choice of anaesthetists, or has he himself a penchant for this surgical procedure? As a general practitioner I do not feel competent to answer; perhaps others will.—I am, etc.,

Glasgow, July 20.

J. W. PATTERSON.

Early Cardiac Massage

SIR.—No one will question the wisdom of Mr. Hamilton Bailey's contention that in the operating theatre at all times everything should be in readiness for the immediate application of injection into the heart and of cardiac massage should these become necessary. Some, however, will be apprehensive lest his article encourage the early use of cardiac massage in non-abdominal cases, before simpler measures have been efficiently tried. I allude especially to immediate and complete lowering of the head. Is Mr. Bailey convinced, for example, that in the case which he describes, when the patient was out of his hands at the moment of collapse, if the boy had at once been inverted and the tongue drawn forward and the chest compressed breathing and circulation would not have started again? As regards adrenaline injection has it not been generally accepted that it is the mechanical stimulus of the needle entering the auricle which is important regardless of any injection fluid?—I am, etc.,

London, July 25.

J. BLOMFIELD.

Da Costa's Syndrome

SIR.—I have read Dr. Paul Wood's illuminating Goulstonian lectures (May 24 and 31 and June 7) with great interest, but there are some points to which I have to draw attention.

In discussing the mechanism of heart pain which is found in the vast majority of patients suffering from effort syndrome, Dr. Wood mentions four different theories; evidently he has overlooked the myalgia of major pectoralis, which in my experience is responsible for heart pain in the majority of cases. I described (*Brit. J. phys. Med.*, 1938, 1, 302) the characteristic "myalgic spots" present in functional heart diseases. In 1940 (*Lancet*, 2, 326) I described these typical myalgic spots again as simulating so-called heart neurosis, and in a case of angina of effort. The myalgic spots are constantly to be found in the origin of major pectoralis near the sternum on the left side in left mammary pain and on the right side in right mammary pain. This origin of heart pain is by no means a theory but a fact which can be verified easily. Since I have been in the Army I could confirm it again and again.

In discussing the question whether the heart pain is local or referred Dr. Wood says: "I have found no evidence in the literature relating to the effect of intramuscular novocain [i.e., injections] on referred pain." In the *Lancet* and the *Practitioner* (1941, 146, 167) I stated most emphatically that novocain injected into a myalgic spot definitely relieves referred pain. I recommended this method not only therapeutically but also as a diagnostic test to prove conclusively that a given pain is referred. The statement, "It is well known that local intramuscular injections of novocain abolish local pain of such lesions as fibrositis," is not correct. On the contrary, in fibrositis or rheumatic myalgias referred pain only is present, and is abolished by injection into the corresponding myalgic spots.

In myalgias of rheumatic, traumatic, or idiopathic (unknown) origin patients complain of referred pain only, which does not coincide with the myalgic spots, of which they are definitely unaware. In all these cases novocain injection into the myalgic spots, not just tender spots but characterized by objective signs, relieves pain almost instantaneously and cures the disease per-

manently. Tentatively I have put forward as a working hypothesis the conception that the myalgic spots are due to a local hypoxia caused by vasoconstriction by reason of stimulation of sympathetic fibres. Since the pathological condition is situated in the muscles, one has to bear in mind the fact that adrenaline has a dual effect, causing vasoconstriction in small doses and vasodilatation in large ones (McDowall, R. J. S., *Control of the Circulation*, London, 1938, p. 268). In my opinion sympathicotonia—a hyperfunction of the sympathetic—is the cause of the effort syndrome. It is known that stimulation of the sympathetic causes a discharge of sympathin (Cannon and Rosenblueth) into the blood, which may or may not be identical with, but is most likely similar to, adrenaline.

I would like to mention here that dizziness may be caused by a myalgia of trapezius, and that breathlessness might be due to the pectoralis myalgia, since it gives rise to pain which is aggravated on breathing. In this connexion it is interesting to mention that ephedrine may produce some of the symptoms of effort syndrome, as anorexia, frequency of micturition, dry mouth, and a changed type of breathing (own experiment).

Owing to lack of space I cannot discuss the many factors which have a bearing on the function of the autonomic nervous system. There is conclusive evidence that the Ca:K ratio influences the sympathetic and parasympathetic in an antagonistic way (Zondek, S. G., *Biochem. Zschr.*, 1922, 132, 362). It is extremely interesting that the same ratio has also a marked bearing on the tone of the capillaries—vasodilatation by Ca excess, and vasoconstriction by K excess (Sollman, T., *Manual of Pharmacology*, 1935, p. 346). In addition the blood vessels are influenced antagonistically by the local pH, being dilated or constricted by an acid or alkaline pH respectively.

Dr. Wood has conclusively shown that fear and emotional strain play a part in the effort syndrome. I fully agree with him but would like to add that these mental factors have a bearing on practically every disease, be it somatic or functional. Nevertheless one is in my opinion not justified in labelling a patient suffering from effort syndrome as psychoneurotic or hysteric. M. B. Bender (*Amer. J. Physiol.*, 1938, 121, 609) experimenting on monkeys, suggests that during fright a discharge of a sympathetic-adrenergic and a parasympathetic-cholinergic substance takes place; hence fear and emotional strain cause a psychosomatic reaction, and not a purely mental one. Neither is it fair to label a patient suffering from "heart pain" as a psychoneurotic, since to him the pain is a real fact and cannot be talked off, even by a heart specialist's assuring him that his heart is healthy. On the other hand, extremely gratifying results are obtained by appropriate treatment of the myalgic spots. On pressure on such a spot we elicit the very pain he is suffering from ("You have got it," the patient sometimes says spontaneously), and injection of a few c.cm. of novocain solution relieves his "heart pain" easily and almost instantaneously, and permanently. This has a double effect in so far as it relieves his pain, and in doing so it convinces him to his own satisfaction that his heart is healthy, thus cutting the vicious circle so well elaborated by Dr. Wood. I am confident that these favourable results can be obtained by every physician who takes the trouble to locate the myalgic spots (not tender spots) and apply the appropriate treatment.

In conclusion I should like to say that it must be our concern to relieve a patient's justifiable complaint, instead of labelling him a psychoneurotic.—I am, etc.,

M. GOOD, M.D.,
Lieut., R.A.M.C.

June 12.

Treatment of Crush Syndrome

SIR,—In view of the high mortality among persons who have been held crushed under debris for some time, whatever treatment they have received, it seems worth while offering a simple suggestion for a line of treatment which I am told has not been tried.

It is possible that some deleterious substance derived from the injured tissues reaches the body as a whole during the time between release from pressure and commencement of treatment in hospital.

All first-aiders are keen to apply tourniquets, and, I am told, apply them in such a way as to stop venous and lymphatic return from the limb. I suggest it would be worth applying a

constriction round the proximal end of a crushed limb, as soon as the limb or part of it is released from pressure, at the site of the incident before moving the patient. If sufficient skill is available, possibly a rubber Esmarch bandage applied tightly to the whole limb from above downward might be considered.

I do not presume to suggest whether the surgeon should amputate, or release the limb from pressure an inch of its length at a time, or gradually diminish the pressure on the limb as a whole.—I am, etc.,

Trowbridge, July 22.

E. CURPHEY.

Lack of Calcium

SIR,—Dr. I. Harris (July 19, p. 102) doubts that adults are suffering from lack of calcium and challenges "the authorities" to exhibit twelve patients with an "unsatisfactory condition of the bones." During the last year alone we have seen three elderly women with generalized osteoporosis complicated by collapse of a vertebral body.—We are, etc.,

GEORGE GRAHAM,
H. JACKSON BURROWS.

London, W.1, July 25.

Persistent Streptococci after Puerperal Fever

SIR,—The following case raises a point of some importance and seems worth recording.

About three weeks ago a man was admitted to hospital with a shallow ulcer about 1 inch in diameter on the ventral surface of his penis, about 1 inch behind the glans. A film from this showed a few pus cells and numerous small streptococci, and the culture was a pure growth of haemolytic streptococci which proved to belong to Group "A."

On going into the possible cause of the infection it transpired that the man's wife had puerperal fever after the birth of a child at the end of February while the patient was away from home on A.F.S. duty, from which he returned about ten days before his admission to hospital. Cultures from the wife's cervix and vagina were taken; the former yielded a pure culture of a haemolytic streptococcus, and in the latter the predominant organism was also a haemolytic streptococcus. Both these strains belong to Group "A."

The three strains were sent to Dr. S. D. Elliott of the Emergency Public Health Laboratory Service at Cambridge and he very kindly Griffith-typed them. All three belong to Type B 3264, a type recognized by Dr. Griffith as a new type which has not yet been assigned a number in the *Str. pyogenes* group.

The persistence of haemolytic streptococci in the cervix and vagina some months after an attack of puerperal fever raises the important point of the advisability of cultures being taken from all such cases to ensure that they do not become carriers. Presumably the woman would become immune to the organisms herself, but would be a potent source of infection at a later confinement.—I am, etc.,

Hastings, July 22.

P. LAZARUS-BARLOW.

The Darning of Hernias

SIR,—I was very interested to read Mr. Rodney Maingot's article (May 24, p. 777) on the floss-silk method of repair for direct inguinal hernias. Most people are agreed that catgut, being an absorbable material, is unsafe to use in the repair of a hernia. After so many days the catgut is absorbed and an undue strain may easily tear asunder the adhesions, not yet firm, left at the site of the catgut stitches. A lattice-work of an unabsorbable material inserted under no tension and forming a permanent framework on which fibrous tissue is laid down will obviously be a much safer method.

The fascia lata method of Gallie is an excellent one and gives very good results. But it entails making a long wound in the thigh and stitching the edges of fascia together after the removal of the required number of the strips, all of which add considerably to the length of the operation. There are a great number of fasciotomes on the market, but on the whole they are most tricky instruments to use. They often go wrong half-way through the operation and one is forced then to cut down; they leave a potential space in the thigh

for a haematoma; and a hernia of muscle occurs through the cut margins of the fascia lata, which can be a cause of great worry to the patient. Floss silk does quite as well as fascia lata, and, what is very important, one can use unlimited amounts, whilst one is limited to a maximum of about four strips, from each thigh, of the fascia.

About a year ago I did a radical cure on a man of 28 for a scrotal hernia *en glissade* (the size of a small football) which contained all his sigmoid colon and a great number of loops of small intestine. It was a hernia which, starting as an indirect, finished as a direct, with a neck some four inches in diameter. It would have been very difficult to do a satisfactory repair with fascia lata in that case. There would not have been enough with fascia, taken even from both thighs. Literally, I used yards of floss silk. The man has since joined the Army as A1.

The danger of a non-absorbable material is, of course, the possibility of sepsis. But if the silk is thoroughly boiled—Mr. Maingot recommends two hours—and then kept in some spirit which is washed off just before the operation, or if one uses the ampoules containing sterile floss silk as sold by John Bell and Croyden, then it is absolutely safe. It is a tragedy when a clean hernia case goes septic. Then the whole surgical ritual should be thoroughly looked into. Some months ago two of my cases in which floss silk had been used unfortunately went septic, and yet both eventually healed up completely without discharging any silk and are dry to-day, some months after leaving hospital. This shows that floss silk can cause no harmful effects, even in the presence of sepsis. I think this is greatly due to the fact that there is no chemical or other substance on the floss silk that by causing a tissue reaction and producing an out-flowing of serum keeps up the discharge from the wound. So once the bacterial infection has died out the wound can heal and stay healed.

I think Mr. Maingot's suggestion of closing the crural canal from above to prevent the possibility of a femoral hernia is an excellent one. It should be reserved for direct hernias, however, when the fascia transversalis is almost non-existent. In indirect hernias it would be unwise to do this as one would have to tear through the fascia transversalis, which is after all a very important barrier to the posterior wall of the inguinal canal.

As man-power for the Services is such a vital consideration at the moment, and as hernias are so frequent in the soldier class, the choice of a satisfactory radical cure becomes a matter of national importance, especially when one remembers the reported recurrence rates—8% to 12% in the best hands. In view of this Mr. Maingot has rendered a great service in bringing up once more this question of the best method of repair of hernias, and I am sure that his floss-silk method will do a great deal in helping to lower the recurrence rate and making men fit for Army duty quicker after their hernia operation.—I am, etc.,

G. STAFFORD MAYER, F.R.C.S.
E.M.S. Surgeon.

Herts, July 22.

Lung Collapse after Eye Operation

SIR,—I was interested in Dr. Roger Lane's case of lung collapse after eye operation (July 19, p. 86). In 1934 (*Trans. ophthalmol. Soc.*, 54, 280) I drew attention to the occurrence of unexplained pulmonary complications after operations on the eye, the clinical picture being dullness and diminished breath sounds at one base with slight fever developing about a week after operation. As physician to Moorfields Hospital I saw many examples of this, and a smaller number of cases in which haematemesis occurred after operations on the eye in patients who had not any previous history suggesting chronic gastric or duodenal ulcer. I suggested tentatively that in both of these groups the visceral disorder might be excited reflexly by the eye operation, the afferent path being the trigeminal nerve and the efferent the vagus. The relationship between the eye and vagus function is close, as we see in the oculo-cardiac reflex and in the vomiting which often accompanies acute glaucoma.

This clinical experience recalls the perforating ulcers of the oesophagus, stomach, and duodenum which may follow experimental lesions of the hypothalamus or, rarely, operations on the brain, and which have been attributed by Cushing and others to a central disturbance of vagal innervation.—I am, etc.,

London, W.1, July 25.

W. RUSSELL BRAIN.

Treatment of Chronic Hypertensive Nephritis by Renal Extracts

SIR,—The annotation in the *Journal* of July 5 (p. 22) on the treatment of hypertension by renal extracts suggests that the case recorded below may be of interest.

A man aged 47 was admitted on October 16, 1940, to the French Hospital under the care of Dr. H. S. Stannus with old-standing chronic nephritis with hypertension; blood pressure 250/120; blood urea 160 mg. per 100 c.c.m.; albumin 10 grammes per litre of urine. Marked anaemia of pernicious type and albuminuric retinitis with almost complete loss of vision in the right eye were also noted. Ordinary methods of treatment availed nothing, and a month after admission two successive attacks of acute oedema of the lungs nearly proved fatal. The blood pressure remained at 230/120; the blood urea had risen to 202 mg. per 100 c.c.m.; muscular twitchings were marked, minor convulsions occurred from time to time, and mental agitation with confusion was present. At the same time almost uncontrollable vomiting was noticed and an acneform eruption (*acné urémique*) remarked.

The administration of renal extract at this point produced rather remarkable effects. Given in the first instance by rectum on account of the vomiting, it was continued by mouth as soon as the vomiting subsided, there being no preparation available for parenteral administration. Three days after the beginning of treatment vomiting ceased, followed by disappearance of the mental and nervous symptoms and lastly the cutaneous manifestations. The patient felt better and looked better; he was once again able to enjoy nourishment. The blood pressure fell to 180/100, but the blood urea continued to rise: 202 mg. per 100 c.c.m. on November 18 to 250 mg. on November 23, 285 mg. on December 2, 300 mg. on December 17, 340 mg. on December 30, 360 mg. on January 7, 388 mg. on January 13, and 420 mg. on January 24, 1941, the day before death. The blood count towards the end revealed 1,500,000 red cells per c.m.m. with 30% haemoglobin. Despite the mounting blood urea the patient remained pretty comfortable to the end and free of the symptoms which had troubled him before the administration of the kidney extract.—I am, etc.,

The French Hospital, London, W.C.2, July 14.

M. BENDIT.

Note by Dr. H. S. STANNUS:

The extract of kidney was used only as a last resort in an attempt to alleviate the distressing symptoms suffered by the patient. The "relief of symptoms" which occurred was quite remarkable, though probably the treatment made no difference in the course of the disease to a fatal issue. Of course, it is not certain that the amelioration in the condition was due to the extract: the constitution of the product is not even known; moreover, the value of a single observation is doubtful. On the other hand, taken as above recorded the case is not without interest as a clinical observation, always remembering the final dictum of Irvine H. Page in the Edward Gamaliel Janeway Lecture for 1941 (*J. Mt. Sinai Hosp.*, 1941, 8, No. 1, 23): "Administration of renal extract is not yet to be considered a practical treatment."

Ether Convulsions

SIR,—May I say to Mr. Dickson Wright (July 12, p. 68), through you, that in my letter (June 21, p. 945) my first object was to describe the features of a typical ether convulsion, and that the description I gave was based upon observations made a good many years ago in a series of six or seven cases. Novocain was not used in any of them. The more recent case which I quoted for completeness (and in which ether was not given deliberately) reproduced this picture so completely that I included it as an ether convulsion. Mr. Dickson Wright tells me that it was a typical novocain convulsion. The natural inference is that the two manifestations are identical—a conclusion supported by Mr. Hamilton Bailey (July 5, p. 32), who also states the attractive hypothesis of a common toxic factor.

Mr. Hamilton Bailey also points out that by the time ether vapour reaches the patient any warmth previously imparted to it has been lost—a statement with which I agree. When I spoke of heated ether I referred to the practice of heating ether in a strong metal container in a hot-water bath to such a tempera-

ture that its vapour is driven off under considerable pressure. I believe that many analyses failed to disclose any toxic agent, and I know that a number of reported cases have occurred under open ether. Despite these facts, the evidence of my own observations points, in the absence of any more convincing evidence to the contrary, towards a toxic factor in the elaboration of which the heating of ether may play an important part.—I am, etc.,

Liverpool, July 22.

CHARLES WELLS.

Treatment of Impetigo Contagiosa

SIR.—The following observations on the treatment of impetigo in Army patients may prove of value to medical officers who are now called upon to treat this class of patient.

In civil life it was my practice to use 5% sulphapyridine ointment in the treatment of this condition, and the results obtained were excellent, cure usually resulting in from three to seven days. Prior to the introduction of sulphapyridine I used the routine method of starch poultice plus lotio cupri-zincica and ung. hyd. ammon. dil., and with this about three-quarters of the cases cleared up within three weeks and the remainder after a more or less prolonged period.

During the last six months I have had occasion to treat quite a number of cases of impetigo contagiosa in soldiers. I first used 5% sulphapyridine ointment, but with very little success, no case healing up completely with its use. I then went on to "alibour" lotion and dilute ammoniated mercury ointment, and again the results were entirely unsatisfactory. The problem then presented itself as to why these two methods of treatment which were so successful in civil life failed to produce the same effect in the Army. A possible solution was suggested to me by my orderly. He observed that in Army patients any ointment will prove unsatisfactory as a therapeutic agent, owing to the fact that the comparatively high-collared tunics have rubbed off the ointment in a very short time and the collar becomes a dirty greasy mess on which no doubt the streptococcus of impetigo finds a good place to incubate and which acts as a focus for the continued spread of the disease.

On active service it would be a considerable nuisance if soldiers suffering from such a mild illness as impetigo had to either go without their tunics or have their face covered with any form of dressing during the day. It was therefore decided to try the effects of an antiseptic lotion alone, and we chose the old-fashioned 1 in 1,000 corrosive sublimate because it was cheap, easily obtained, and sufficiently easy to make up for any unqualified dispenser. This has proved a very satisfactory method of treatment. The lotion is dabbed on three times daily, the man shaves every third day and has his razor and brush sterilized by the orderly in the medical inspection room immediately after shaving. The face is uncovered during the day, but an aseptic dressing is put on at night to prevent spread by means of the pillow. By this method it has been found possible to cure most cases of impetigo in Army patients within ten days.—I am, etc.,

July 21.

E. SNELL, Lieut., R.A.M.C.

Chronic Sick

SIR,—Very reluctantly I ask you to publish one more letter from myself on the subject of the "chronic sick." I say reluctantly because a week ago I had quite made up my mind that the "chronic sick" had very few friends either in the Ministry of Health, among medical members of Parliament (with the striking exception of Sir E. Graham-Little), or in the medical profession generally, and therefore it was a mere waste of time pursuing the subject any further.

In your issue of July 19 (p. 100), however, there appears a long letter from Dr. Leonard G. Parsons upon which I should like to make several brief observations. The main body of the letter is devoted to various comments and criticisms of a letter in the *Journal* of June 28 (p. 987) from "De Senectute." I am not concerned to defend "De Senectute"; no doubt, whoever he is, he can look after himself. But I am concerned with those parts of Dr. Parsons's letter which refer (a) to the occupation of beds by the evacuated chronic sick which were "provided for acute and Service sick and air-raid casualties," and (b) to the nursing of the chronic sick by "members of the C.N.R., Red

Cross, and Order of St. John," as well as his suggestion that auxiliary hospitals are unsuitable for the care of the chronic sick.

With regard to (a) the comment I wish to make is that this is only another example of the incompetence and unpreparedness of the Ministry of Health in all matters concerning the measures which should have been taken long before war broke out to provide suitable accommodation in the less vulnerable areas not only for the chronic sick but for many other types of evacuees. Ordinary common sense, foresight, and prudence, which should have characterized the work of the Ministry of Health, were simply not there. If they had been it would not have been necessary to take "panic measures" a year or more after war broke out to provide suitable accommodation outside our great industrial towns for evacuees of all kinds, including the "chronic sick," aged and infirm, and young children. But what happened was that those who were then responsible for the policy of the Ministry were so obsessed with the notion that the only thing they had to think about was hospital accommodation for "30,000 casualties per day" in London alone that the staff concerned could think of nothing else. In these circumstances it is easy to understand how it came about that when "chronic sick" patients were being killed in their beds in large public institutions in London and elsewhere by direct bombing the Ministry adopted the usual "panic measures" and rushed patients of this kind off to hospitals in the less vulnerable areas, where beds had been set aside for the acute sick, casualties, etc.

With regard to (b) I do not agree with Dr. Parsons that auxiliary hospitals are unsuitable for the chronic sick. At least that is not my own experience. I have seen a good many auxiliary hospitals which would be eminently suitable; but I do not suggest that all of them are, for the simple reason that I have not seen them. On the other hand, there are nearly 200 auxiliary hospitals in England and Wales, with a total accommodation of nearly 12,000, and most of them are empty and likely to remain so; if properly used I do not see why there should be any practical difficulty over the staff question. No one with any knowledge of the skill and patience and tact required to nurse the "chronic sick" would for one moment suggest that they should be nursed by V.A.D.s, etc. The obvious course to adopt is to transfer the medical, nursing, and all other staff who have been looking after the "chronic sick" to the new accommodation whenever provided, and I am unable to understand why this course should not be adopted as part of the scheme of transfer. It is quite true that the work could not be undertaken by the Joint War Organization of the B.R.C.S. and Order of St. John. It is obviously unsuitable work for such a voluntary body. What would be required would be simply that the Joint War Organization and the Ministry of Health should agree that certain of the existing auxiliary hospitals should be transferred for the duration of the war to the local public health or local public assistance authority for the special purpose of providing for the "chronic sick." I do not say that such a step would solve the problem, but it would go a long way towards it.—I am, etc.,

Criccieth, July 19.

FREDERICK MENZIES.

Physical Medicine and Orthopaedics

SIR,—Now that all your correspondents seem to have said their say about the practitioners in physical medicine and their art and science, may I, as one of the elder of the genus in this country—save, of course, for the Spa practitioners—wind up with a few notes.

First, let me say how gratifying it has been to watch the interest that your original annotation has evoked. Thirty years ago the correspondence which followed would have been unthinkable, so few would have been the numbers of those with adequate knowledge to write. Even our critics have shown the importance they attach to our activities.

With regard to status, all that need be said is that our art is, or should be, the handmaid of the profession as a whole. Few indeed can be the number of our fellow practitioners who, had they adequate knowledge, could claim that the art of physical therapy could find no useful place in the treatment of their patients during some stage of illness and disability or during convalescence therefrom. Obviously, therefore, the term

"orthopaedic physician" is a poor, inadequate description for us. The orthopaedic surgeon may, it is true, find that—*pace* Böhler—physical therapy is applicable to the vast majority of his cases with advantage; not infrequently without it his surgery would be useless. This is the reason why most of them study the elements of physical therapy, but mere acquaintance with those elements does not fit them to prescribe all that is best in physical therapy for their patients. We hold, as a standard of efficiency, that we cannot honestly prescribe any treatment which, without aid, we are unable to perform for ourselves at least as efficiently as those to whom the work is entrusted. Otherwise how can we prescribe with accuracy and precision, or judge by results whether progress is the best obtainable? If barely acquainted with the elements, how then can orthopaedic surgeons demonstrate technique to the masseur or masseuse, or judge of the finesse of technique? The physician or surgeon, orthopaedic or otherwise, who relies on his knowledge, or often lack of it, even in regard to what can only be termed by us as the "beggary elements," cannot expect the best of treatment for his patients, or grumble if they, in despair, seek ultimate relief from adequate physical medicine.

Staff status is another story—no one can expect election to staff rank by his colleagues till he has proved his worth and, perhaps more important, his ability to co-operate with them. It is granted readily enough when this has been done, and what more can we ask or expect? We are getting on. A very few years ago no practitioner of physical medicine had been elected to the Fellowship of the Royal College of Physicians; now there are five at least.

Finally, may I pay tribute to the members of that magnificent body the Chartered Society of Massage and Medical Gymnastics for the part they have played in the advancement of physical therapy? When I first became acquainted with their activities in 1907 there were some 700-odd members; now there are 12,814—surely a striking testimony to their usefulness and efficiency. Without their aid and loyalty to our profession physical therapy could not have known the yearly advance in technique which takes place, nor could the practitioners of physical medicine have advanced in numbers, knowledge, and experience to the extent that has in fact occurred.

There is, however, one outstanding weakness in physical medicine which must be overcome before it finally comes into its own. This is that there is no general standard of knowledge required of us in all the different branches of our art to merit our designation as practitioners of physical medicine. There is as yet no course of training available which fully covers the whole field. Hence some of us are experts in hydrotherapy, others are mainly electrotherapists, while yet others are more skilled in actinotherapy or in manipulative treatment, be it of soft parts or of joints. Expert knowledge of all branches of our art cannot be expected of all of us as yet, and before the art can be attained the science is essential. Some day in the near future this deficiency will be remedied. Even as we are we can be of service; in the future we shall be more so; and meanwhile, if some of our medical colleagues find no use for us, the general public continues to do so and to insist on their advisers co-operating with us.—I am, etc.,

JAMES MENNELL.

London, N.W.1, July 20.

* This correspondence is now closed.—ED. *B.M.J.*

Medical Planning

SIR.—In the *Journal* of June 21 (p. 942) it is reported that the president of the Faculty of Radiologists, Dr. Cochrane Shanks, referring at the annual meeting of the Faculty to his position as the Faculty's delegate to the B.M.A. Planning Commission, promised to send a questionnaire among the members of the Faculty asking them, under seal of anonymity, to give such facts about their work as they felt disposed to divulge; also to give him their views on what alterations and improvements were called for in the radiological services of the district. This step is undoubtedly to be welcomed and recommended to other members of the Planning Commission, particularly if they would couple it with a declaration that no action would be taken until a policy had received sanction of a fully informed medical profession.

Doubtless certain of the apprehension given to the Planning Committee arises from the fact that it is by no means unknown for an inadequately informed public to be committed by virtually self-elected bodies to policies which may produce results entirely different from those desired by the majority. What has happened not once but many times may well happen again. Without intending to criticize any member of the Commission either directly or indirectly in their voluntary acceptance of a task, onerous, difficult, and likely to be thankless, it is permissible to ask for it to be made known to those who are directly concerned how selection of this committee was brought about or what arrangements will be made to secure full representation of every member of the profession.

A large number of doctors to whom I have spoken have a viewpoint best described as "apprehensive" of the outcome of all this planning, but unfortunately almost invariably coupled with it is a feeling of hopeless resignation. They are not prepared to do anything to alter their future, let alone take the time and trouble necessary to seek causes for a state of affairs which they regard as becoming extremely unpleasant. A review of the letters over the past few months in the *Journal* shows that the greater number fluctuate between the Scylla of an "improved" panel system and the Charybdis of undefined State Medical Service. Is this not the unmistakable result of the organized propaganda and subtle distortion of fact which tries to make it appear that the only alternative to-day facing the British peoples is military domination by Nazism or a generation of vicious and intolerable taxation in an impossible attempt to pay a second or a third time or even more for a war which then will have been paid for in "blood, toil, tears, and sweat"?

It is this perfect parallel with world affairs which makes it a certain prediction that no satisfactory outcome can arise from the activities of the Planning Commission unless a revolution in public thought and action causes the complete subjection of those responsible for a policy which over the past fifty years has been gathering control of personal initiative to its own keeping, planning to assign the national and individual sovereignty of this people to a completely centralized and world-dominating economic federation. The facts are beyond all disproving and the conclusions arresting. I venture to predict that a mass of evidence could be placed before the Medical Planning Commission proving the urgent need of the moment is not detailed Utopian planning for the future of medicine but an active awakening of democratic control and a bonding of medical opinion with a policy based on an undistorted conception of realities.

The doctor cannot control the policy of his institutions if they are too large, nor can he direct their successful functioning if they remain dependent on the arbitrary grants by centralized interests of the financial credit necessary for them to carry out their work. Control of policy has been steadily taken from the doctor. Faced with a deliberately produced diminution of private practice and an extending panel system or State service, the real result is a restriction of personal initiative. A policy of such nature does not exist by chance and must be reversed if existence is to be tolerable.

The best work the Planning Commission could do would be to awaken the members of the medical profession to the truth that their future depends on their own efforts to secure in every sphere a policy which unites personal responsibility with power; which everywhere matches physical ability to produce results needed with financial ability to do it—policies which dispense with bureaucracy and "red tape." Then we can build a future worthy of our heritage.—I am, etc.,

Belfast.

DOUGLAS BOYD, M.B., D.M.R.E.

The report for 1940 of the St. John Ophthalmic Hospital, Jerusalem, shows that work, despite war conditions, was heavier than ever. In-patients numbered 926, an increase of 234 over the previous year, and the total attendances in the out-patient department numbered 119,986, which constitutes a record for the hospital, and new out-patients were 21,252. The work on the new south block has been proceeding satisfactorily. The Order of St. John has offered it to the Government of Palestine for the duration of the war to be used as a civilian casualty hospital, and the offer has been gratefully accepted.

Obituary

SIR WILLIAM WILLCOX

Dr. J. D. Rolleston writes:

Beyond the statement that he served on a special committee at headquarters on tests for drunkenness the otherwise excellent obituary of Sir William Willcox in the *Journal* of July 19 (p. 103) contains nothing to indicate the interest which, without being an abstainer, he always took in the alcohol problem. In particular no mention is made of his connexion with the Society for the Study of Inebriety, of which he was president from 1924 to 1927. In 1923 he delivered the Norman Kerr lecture before this society, his subject being drug addiction, and in 1924 his presidential address was devoted to the aims and work of the society. He also always took an active part in the discussions held at the society's meetings. Furthermore he contributed an article on the medical aspects of temperance to a book entitled *Confirming the Facts*, recently published by the Temperance Collegiate Association, and containing articles by Sir Frederick Gowland Hopkins, Prof. Amy M. Fleming, Mr. W. McAdam Eccles, Lord Stamp, Sir Leonard Rogers, and others.

Early this year the liner on which Dr. HILDA CRICHTON BOWSER was returning to India was shelled in mid-ocean by a German surface raider. Most of the lifeboats were thus damaged and fellow passengers have reported that Dr. Bowser was in one which had been seen to sink. The more seaworthy boats were too full to rescue survivors, who had to be left in the water in the hope that they would be picked up by a boat which had been launched from the raider. This hope has proved vain, and the Baptist Missionary Society and a wide circle of friends now mourn the loss of the Society's senior medical missionary in India. Dr. Bowser was the daughter of the late Principal of the Midland Baptist College. She took her B.Sc. degree from Nottingham University College before entering the London School of Medicine for Women, where she qualified M.R.C.S., L.R.C.P. in 1919 and later took the M.B., B.S. of London University. Relinquishing her studies for the degree of M.D. in obstetrics she sailed in 1923 to India, and for eighteen years built up a unique hospital and nurses' training work at the Rahmatpur Women's Hospital at Palwal in the South Punjab. Her reputation and influence were felt in a wider circle in India. She represented the Association of Medical Women on the governing board of the Lady Hardinge Medical College in Delhi, and acted as chairman of the North India Board for Nurses' Examinations. She maintained the highest standards of professional work, and the reports of Government inspectors invariably praised the efficiency of what was considered as a model rural hospital. Physically robust—a college and county hockey captain—and possessing great mental vigour, Dr. Bowser was the embodiment of the ideal of "mens sana in corpore sano." Her gifts and graces were wholly dedicated to a life of service. It is men and women like Hilda Bowser who are responsible for the fact that the phrase "missionary spirit" has found a place in the vernacular of a country which needs and greatly admires the spirit of the Good Physician.

We regret to announce the death after a long illness, on June 13 at the age of 74, of Hofrat Professor JULIUS ZAPPERT of Vienna at Slough, where he had been living in exile for the last two years. His chief work was concerned with the neurology of children, his principal publications being devoted to Heine-Medin's disease (1911), diseases of the nervous system in childhood (1922), convulsions in childhood (1928), and post-vaccinal encephalitis in conjunction with Dr. Marius Kaiser which received notice in this *Journal* (1939, 1, 59).

The following practitioners have died abroad: Dr. LARS WILHELM FAGERLUND, a Finnish anatomist and epidemiologist, author of numerous works, especially on medical jurisprudence, leprosy, and tuberculosis, aged 87; Dr. JOHANNES WILHELM HJELMANN, a Helsingfors dermatologist and syphilologist, aged 79; and Dr. LLOYD VERNON BRIGGS, past president of the New England Society of Psychiatry and former director of the Massachusetts Society of Mental Hygiene, aged 77.

Universities and Colleges

UNIVERSITY OF OXFORD

The first examination in Special and Clinical Pathology begins on September 30, and names must be received at the University Registry by 3 p.m. on Wednesday, September 10. The attention of candidates is drawn to the facts that: (1) Certificates 4 and 10b must be produced. The former is to the effect that the candidate has been instructed in special pathology, including post-mortem examinations, and clinical pathology for a period of not less than eighteen months. The latter is to the effect that the candidate has completed twenty-one months of systematic clinical instruction. (2) They must also offer forensic medicine and public health unless they have already passed in it.

UNIVERSITY OF LONDON

The Principal's Report

The report of the Principal, Mr. H. L. Eason, on the work of the University during the year 1940-1 has now been printed, and much of it is naturally concerned with the war and its effects upon academic life in general, on teaching and research, and on the buildings of the university and its constituent schools. In his introduction Mr. Eason notes that the results of intensive air raids on London have fully justified the policy of dispersal generally adopted in the summer of 1939. The damage to university buildings has been so severe and so widespread that if the schools had still been in London the work of the internal side of the university would have practically come to an end for the time being. University College has suffered very badly, and one of the more recent sufferers is the London School of Hygiene. The hospitals attached to the medical schools of the university have almost without exception been severely damaged, but owing to the decentralization of staffs, students, and patients under the Emergency Medical Service, medical education has been maintained at a high level. The greatest sufferers among the medical schools have been St. Bartholomew's and the London School of Medicine for Women. Notwithstanding all the handicaps under which it has laboured, by reason of war damage, decentralization, and delays and difficulties due to disturbance of communications, the work of the university has been well maintained, and normal examinations have been held, though in some cases in provincial centres. The Principal conveys the grateful thanks of the University of London to all those provincial universities and university colleges which have hospitably entertained staff and students and enabled the examinations to be carried on without material loss of efficiency. Among many miscellaneous items mentioned in this report are the foundation by Dr. T. H. Sanderson-Wells of prizes in the pathology and physiology of food, and funds for an occasional lecture on human ailments with special reference to soil fertility; the appointment of Dr. J. H. Gray to the chair of anatomy at St. Mary's on the retirement of Prof. J. E. S. Fraser; and special work of therapeutic value developed in connexion with the military and E.M.S. hospitals. In conclusion Mr. Eason writes: "This report necessarily deals in a scattered way with a scattered university. While exile has its disadvantages both for staff and students, it has its advantages in stimulating adaptability to circumstances and in providing an education in its methods, habits, and customs of universities other than one's own. Our students and teachers have certainly not sat down by the waters of Babylon and wept."

GUY'S HOSPITAL MEDICAL SCHOOL

The following awards have been made for 1941: Entrance Scholarship in Arts (value £100): E. L. W. Leiser. Entrance Scholarship in Science (value £100): Divided between J. C. Crook and D. D. Hilton.

UNIVERSITY OF EDINBURGH

A graduation ceremony was held on July 16, when the following degrees and diplomas were conferred:

M.D.—³D. S. Fairweather J. A. Farfor, Captain, R.A.M.C., ¹C. A. Green, ¹D. Harley, A. G. MacGillivray, ³H. Miller, Surgeon Lieutenant, R.N.V.R., A. Paterson, A. I. Ross, ²W. S. Thomson, Lieutenant, R.A.M.C.

Ph.D.—A. E. Sundareson, M.B., B.S.

M.B., Ch.B.—P. A. Adam, R. S. F. Adam, W. J. Aitken, F. G. Alexander, W. G. Alexander, A. Anderson, W. Anderson, Winifred A. Bailey, Helen S. Barrett, C. L. Bikitsha, E. C. B. Bramwell, A. S. Brown, I. G. Brown, J. B. Brown, M. L. Brown, R. Brown, Maud L. Buchanan, G. M. Carstairs, Josephine A. Cartwright,

T. M. Chalmers, Edith M. Churchward E. A. Claireaux, J. R. Clark, L. E. S. Coghlan, O. C. Colt, J. F. Cowan, J. D. Crombie, Rosina G. Dabb, A. B. da Costa, W. J. E. Darling, Esther A. Davidson, F. B. Davidson, J. Davidson, J. R. Deuchars, H. S. Dewar, J. S. Drummond, J. W. Drummond, A. D. Drysdale, E. C. Eadie, Ethel F. Edwards, A. W. G. Elliott, Esther T. Ewing, E. C. Field, D. E. P. Forbes, W. R. Fyvie, T. M. L. Galloway, M. Gandz, J. A. L. Gilbert, I. C. Godfrey, J. M. Gold, I. W. B. Grant, Marie P. S. Grant, A. A. Guild, D. S. Harling, Elizabeth G. Harris, K. W. Horn, H. Hutchison, Katherine I. Izat, D. Jaboor, P. M. Kerr, A. M. Langwill, J. R. Lauckner, J. Lawson, P. B. Lockhart, Philippa M. Ludlam, J. M. M'Alpin, J. M'Clernont, R. N. C. M'Curdy, H. MacL. T. MacDonald, J. A. Macfarlane, R. C. M'Laren, I. MacC. MacLeod, G. C. Malloch, K. L. Marks, Margaret St. C. Masson, Ellis M. Matthew, F. G. Maxwell-Smith, J. C. G. Mercer, A. M. Merriweather, Grace M. Mitchell, R. C. E. Moffat, A. G. C. Neill, D. F. Nicholson, J. Orr, C. A. Palfrey, R. B. Parker, W. H. Parkinson, J. M. D. Paterson, M. G. Pearson, H. J. Powell, J. W. T. Pretsell, T. Primrose, V. T. Pugh, B. C. E. Richardson, M. R. Rifaat, Winifred B. Ritchie, W. G. Robertson, H. E. Robins, H. N. Robson, J. D. Ross, J. Y. W. Russell, A. J. Sangster, Sheila P. V. Sherlock, O. H. Siung, Betty V. Slesser, J. D. A. M. Smart, A. C. Smith, C. J. C. Smith, Margaret Sinclair Smith, Margaret Steele Smith, J. C. W. Somerville, J. J. Stevenson, N. R. Stewart, J. R. Stuart, A. P. Tait, Helena P. M. L. Taylor, Mildred S. Tie-Ten-Quee, T. Tie-Ten-Quee, J. E. Tinné, W. H. Toms, Janet C. Trotter, Davina M. van Weel, J. W. Walford, Margaret J. P. Walker, Grizel Warnock, Elizabeth M. Watson, W. B. Whiston, J. G. Whitty, J. Wilkinson, Jean C. Willison, J. A. C. Wilson, Sara S. Wood, H. C. Worrall, Kathleen M. F. Worrall (née Whalley), R. K. W. Yang, W. W. Yellowlees.

D.P.H.—Olive B. Burnetson, G. A. R. Brown, W. D. Buchanan, J. J. Cameron, Monica de S. Craig, W. Giles, Rachel Hunter, R. P. Seymour, M. A. Smeaton, Mona M. F. Thomson.

DIPLOMA IN MEDICAL RADIOLOGY.—K. Brauer, B. Donnelly, G. H. Illingworth, J. A. Wain.

¹ Awarded gold medal for thesis. ² Highly commended for thesis. ³ Commended for thesis. ⁴ Passed with honours. ⁵ In absentia.

The following prizes were presented:

MacLagan Prizes in Forensic Medicine: D. Henderson and R. T. S. Louttit. Straits Settlements Gold Medal: W. F. E. Baumann. Elliot Scholarship and Leslie Medal, Scottish Association for Medical Education of Women Prize, Moulton Scholarship in the Practice of Physic, Dorothy Gilliland Memorial Prize, Beatty Prize in Anatomy and Surgery, Keith Memorial Prize in Systemic Surgery, and Murdoch Brown Medal in Clinical Medicine: Sheila P. V. Sherlock. Buchanan Scholarship in Midwifery and Gynaecology and Annandale Medal in Clinical Surgery: Josephine A. Cartwright. James Scott Scholarship in Midwifery and Gynaecology: J. Y. W. Russell. Conan Doyle Prize: W. R. Fyvie. Wightman Prize in Clinical Medicine: A. M. Merriweather. Paterson Prize in Clinical Surgery and Thomson Memorial Medal in Child Life and Health: J. A. L. Gilbert. Sir Humphry Rolleston Prize: J. Orr. Murchison Memorial Scholarship in Clinical Medicine: A. A. Guild. Ellis Prize in Physiology: A. E. Ritchie. Gunning Victoria Jubilee Prize in Chemistry: G. T. Meiklejohn. Gunning Victoria Jubilee Prize in Materia Medica: G. A. Levy. Gunning Victoria Jubilee Prize in Medicine: J. Innes. Lewis Cameron Undergraduate Prize in Bacteriology: B. Crickshank. Biggam Medal and Prize in Pathology: H. T. G. Sawbridge. Cunningham Memorial Medal and Prize in Anatomy: P. R. Walbaum. Whiteside Bruce Bursary: A. D. Bethune and Constance C. Forsyth (equal). Vans Dunlop Prize in Botany and Zoology: Constance C. Forsyth and Hilary F. H. Hamilton (equal).

POLISH SCHOOL OF MEDICINE AT EDINBURGH

The degrees of M.B., B.Ch. were conferred on K. Bazarnik, Lieutenant-Pilot, Polish Air Force.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the Royal College of Surgeons of Edinburgh held on July 21, with Dr. H. M. Traquair, President, in the chair, the following, who had passed the requisite examinations, were admitted Fellows:

F. P. Cameron, Lyra M. de Souza, K. Fraser, J. W. Frost, W. J. F. Guild, Ethna W. Little, G. E. Moloney, D. M. Morrissey, K. D. Rao, E. W. Somerville, B. G. Spiers, W. S. Tulloch.

CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the final examinations, have been granted the diploma of L.R.C.P.Ed., L.R.C.S.Ed., and L.R.F.P.&S. Glasg.:

N. V. Appavoo, H. K. Banda, F. H. Batchellor, S. J. Blau, A. H. Brambir, W. Brown, M. Burdman, D. Davidson, W. J. Dempster, H. H. Feldman, W. J. E. Fernandez, J. Fitzsimons, S. Gelband, E. G. Gordon, H. P. Hall, H. V. Hankins, A. S. B. Hebron, M. H. Hurwitz, J. Ireland, L. Kaywin, H. Laret, M. Links, E. Lipschik, M. K. McCabe, A. McCall, T. McMurray, J. C. MacWilliam, I. Markowitz, H. Pearl, J. M. Stewart, L. J. Swirsky.

E. Nobel, a graduate of a recognized foreign university, was also admitted a Licentiate.

The Services

DIRECTOR-GENERAL, ARMY MEDICAL SERVICES

Colonel (Temporary Brigadier) Alexander Hood, C.B.E., has been appointed Director-General, Army Medical Services, in succession to Lieutenant-General Sir William P. Macarthur, K.C.B., D.S.O., O.B.E., who retired on August 1.

The new Director-General graduated in medicine at Edinburgh University in 1910 and took the M.D. degree in 1931. He entered the R.A.M.C. in 1912 after serving as house-surgeon at the Edinburgh Royal Infirmary. He has been D.D.M.S. in France and D.D.G. at the War Office.

HONORARY SURGEONS TO THE KING

Surgeon Rear-Admiral G. F. Syms, R.N., has been appointed an Honorary Surgeon to the King.

Colonels T. C. Boyd, V.H.S., and H. J. M. Cursetjee, D.S.O., V.H.S., I.M.S., have been appointed Honorary Surgeons to the King, vice Colonel J. Taylor, C.I.E., D.S.O., I.M.S. (ret.), and Major-General N. M. Wilson, C.I.E., O.B.E., I.M.S. (ret.), respectively.

ARMY AWARDS

Major F. McL. Richardson, R.A.M.C., has been awarded the D.S.O. and has been mentioned in dispatches, and Captains H. S. Ahluwalia and M. C. L. Smith, I.M.S., have been awarded the M.C. in recognition of gallant and distinguished services in the Middle East.

MENTIONS IN DISPATCHES

Surgeon Lieut. John Ffrangcon Roberts, R.N.V.R. (H.M.S. *Rosaura*) has been posthumously mentioned in dispatches for gallantry in saving a wounded shipmate.

COMMENDATION

Lieut. Frederick Graham Millar, R.A.M.C., has been commended for brave conduct.

CASUALTIES IN THE MEDICAL SERVICES

ROYAL ARMY MEDICAL CORPS

Lieut. ANTHONY JAMES MOON, who was reported missing in s.s. *Lancastria* in June, 1940, is now presumed killed. He qualified M.R.C.S., L.R.C.P. in 1936, and took the degrees of M.B., B.Chir. of the University of Cambridge in the following year. Before the war he was in practice at Wallington, Surrey.

War Substantive Captain ROBERT MONTGOMERY MAXWELL, who has died of wounds, received his professional education at the University of Glasgow, where he graduated M.B., Ch.B. in 1936. His home was in Glasgow.

Prisoners of War

Captain Alfred Ruff Darlow.

War Substantive Captain Harry Acroyd Barker.

Lieut. James Alexander Savage Mulligan.

DEATHS IN THE SERVICES

Major-General SIR OWEN EDWARD PENNEFATHER LLOYD, V.C., K.C.B., late R.A.M.C., died at St. Leonards-on-Sea on July 5, aged 87. He was born on January 1, 1854, the son of Major M. P. Lloyd of the 58th Foot and of Col. Roscommon, was educated at Fermanagh College, at the Queen's University, Cork, and in the school of the Edinburgh College of Surgeons, taking the L.R.C.P.&S. Ed. in 1877. He entered the Army as surgeon in 1878, became full colonel in 1905, surgeon-general in 1909, and retired in January, 1914, but rejoined as soon as war broke out in August, 1914, and served as D.M.S. of the Southern Command. He won the V.C. in the Kachin Burma expedition of 1892-3, received the C.B. in 1910, and was promoted to K.C.B. in 1919. From 1922 to 1924 he was a colonel commandant of the R.A.M.C. During his first year of service he took part in the Zulu War of 1879-81, and was present at the storm and capture of Sekukuni's stronghold, receiving the medal and clasp. In the first Boer War of 1880-1 he formed one of the garrison of Standerton, which held out against a superior force of Boers till the end of the war. During the Burmese War in 1892-3 he won the V.C. for his share in the defence of the Siva post in the Kachin Hills. The announcement in the *London Gazette* read as follows: "During the attack on the Siva post by Kachins on January 6, 1893, Surgeon-Major Lloyd, on hearing that the C.O., Captain Morton (who

had left the fort to visit a picket about 80 yards distant), was wounded, at once ran out to his assistance under a close and heavy fire, accompanied by Subadar Singh. On reaching the wounded officer, Surgeon-Major Lloyd sent Subadar Singh back for further assistance, and remained with Captain Morton till the Subadar returned with five men of the Magwe Battalion of Military Police, when he assisted in carrying Captain Morton back to the fort, where that officer died a few minutes afterwards. The enemy were within 10 or 15 paces, keeping up a heavy fire, which killed three men of the picket and also Bugler Purna Singh. This man accompanied Captain Morton from the fort, showed great gallantry in supporting him in his arms when wounded, and was shot while helping to carry him back to the fort. The native officer and five sepoys above alluded to have been awarded the [Indian] Order of Merit." After Captain Morton's death Surgeon-Major Lloyd took command of the fort and brought the fight to a successful issue. He served afterwards as medical officer to the Franco-British Boundary Commission on the Mekong River in 1894-5, and in the same capacity on the British-Chinese Boundary Commission on the Burmese frontier in 1898-9, acting for a time as commissioner in the place of Sir George Scott. On his return to England he served as senior medical officer of the Dover Garrison and District. In 1905 he returned to India as principal medical officer of the Bareilly Brigades, when he was appointed Honorary Surgeon to the Viceroy. Subsequently he served for a short time as principal medical officer in South Africa. He had been a member of the British Medical Association for twenty-two years.

Major-General Sir WILLIAM WATSON PIKE, K.C.M.G., D.S.O., R.A.M.C. (ret.), died at Lincoln on June 26, aged 81. He was born in Co. Mayo on March 10, 1860, the son of the late Mr. W. Pike of Glendaray, and was educated at Dublin, taking the L.R.C.P. and S.I. in 1880 and the F.R.C.S.I. in 1888. In his student days he was a famous rugby international, playing at three-quarter back in the Irish team on several occasions. He entered the Army as surgeon in 1882, reached the rank of full colonel in 1911, was specially promoted to surgeon-general for distinguished war services in 1917, and retired in 1920. He served throughout the South African War of 1899-1902, when he took part in the relief of Kimberley; in operations in the Orange Free State, including the actions of Paardeberg, Poplar Grove, and Dreifontein; in the Transvaal, including actions at Pretoria; and in Cape Colony; was twice mentioned in dispatches and received the Queen's medal with five clasps, the King's medal with two clasps, and the D.S.O. In the war of 1914-18 he served first as A.D.M.S. of a division, then as D.M.S. of a corps, but in 1917 as D.M.S. of the Fourth Army. He was then sent to East Africa to confer with General Smuts on the medical organization of the troops in that theatre of war. In 1918-19 he was serving in India on special duty and on his return home was made a K.C.M.G. Before receiving this honour he was mentioned in dispatches three times and received the C.M.G. as well as a special promotion. Sir William Pike had been a member of the British Medical Association for thirty-five years. In 1886 he married Sara Louisa, daughter of Mr. E. Wheatley; she died in 1918, leaving a daughter who married Colonel O. Y. Hibbert, and died in 1935.

Lieutenant-Colonel DAVIS HERON, C.I.E., I.M.S. (ret.), died suddenly at Ashridge Hospital on June 24, aged 63. He was born in January, 1878, and was educated at the University of Edinburgh, where he graduated M.B., Ch.B. in 1900. He took the F.R.C.S. Ed. in 1912. After filling the post of house-surgeon at Scarborough Hospital and Dispensary and serving as a civil surgeon in the R.A.M.C. in 1901-2, entered the I.M.S. in 1903, became lieutenant-colonel in 1922, and retired in 1930. He served during the war of 1914-18, was mentioned in dispatches in 1917, and received the C.I.E. in 1918. He had been a member of the British Medical Association for thirty-five years. He leaves a widow.

On production of a certificate from the doctor or midwife who has been booked to attend a confinement, or, in the case of a woman attending an ante-natal clinic, from the medical officer of health, expectant mothers will be supplied by welfare authorities with fifty coupons to buy materials for garments, which should be made before the baby is born. The certificate, which should be given as soon as the diagnosis is made (usually the sixth month of pregnancy), should state the mother's name and address, her National Registration number, and the approximate date on which the confinement is expected. Double the number of coupons will be issued where a positive diagnosis of twins has been made and confirmed.

Medical Notes in Parliament

In the House of Lords on July 22 the Royal Assent was given to the Finance Act. In the House of Commons on the same day the National Health Insurance, Contributory Pensions, and Workmen's Compensation Bill passed its remaining stages.

Pharmacy and Medicines Bill

The House of Commons in Committee amended the Pharmacy and Medicines Bill on July 15 and 16.

On Clause 3 (Prohibition of advertisements relating to certain diseases) Mr. PETERS moved to add to the list of those to whom prohibited advertisements might be sent persons who, although not registered practitioners, were engaged in medical research. Mr. ERNEST BROWN said the clause was a fundamental one to prevent sufferers and their relatives being imposed on by advertisements of useless remedies. The amendment was too vague. He would be glad to discuss with Mr. Peters any proposal affecting a definable group. The amendment was withdrawn.

Dr. RUSSELL THOMAS criticized the list of diseases cures of which were not to be advertised. He said the number of people suffering from locomotor ataxy was so small that it would not pay to advertise cures for it. There was nothing to prevent the patient taking advertised cures for neuritis and dizziness for years till this disease was diagnosed. Similarly persons suffering from diabetes used all sorts of patent remedies for their weakness until their disease was diagnosed. The clause would have no effect on the advertising campaign for debility and weakness. The inclusion of glaucoma was futile. No vendor of patent medicines would say he had a cure for cataract or glaucoma, but there would be ample scope for the patent medicine vendor to advertise remedies for the symptoms. In the case of Bright's disease there was every field before the disease was diagnosed for the vendors of patent medicines to sell wares for the treatment of slowly developing symptoms. The inclusion of Bright's disease would have no effect on the patent medicine trade. The same thing applied to epilepsy and paralysis.

Miss HORSBRUGH said the clause would make illegal the advertising of specific articles as cures for particular diseases, not the treatment of those diseases. Proceedings would not be taken except with the consent of the Attorney-General or Solicitor-General.

DISCLOSURE OF INGREDIENTS

Mr. JAMES GRIFFITHS moved to provide that the disclosure must be in English. Dr. RUSSELL THOMAS said a famous pill whose composition in Latin would read something like: "Sap. moll., ext. aloin; zingiberis" would probably not flourish so much if on the wrapper in plain English were written: "Soap, aloes, and ginger." Mr. BROWN said disclosure should be made in terms clearest to those who had scientific knowledge and to those who bought. He had an amendment to leave out "composition" and to insert "accepted scientific name or other name descriptive of the true nature." He would go into the matter again before the Report stage. Mr. James Griffiths then withdrew the proposal that disclosure must be in English, and the House accepted Mr. Brown's amendment.

The House negatived an amendment, proposed by Sir THOMAS MOORE on behalf of the Society of Herbalists, which would exempt from detailed disclosure a remedy composed of a non-poisonous plant or plants.

On the motion of Captain ELLISTON the coming into force of the Act was delayed from January, 1942, to July, 1942, to give a sufficient period for disposal of stocks.

On Clause 9 (Repeal of medicine duties) Sir FRANCIS FREMANTLE said his friends agreed to this clause only if other conditions were laid down for complete and effective control of advertisements and the disclosure of ingredients. When the Purchase Tax was removed there would be a case for resuming the taxation of medicines.

ENFORCEMENT OF THE BILL

Mr. BROWN proposed a new clause authorizing food and drugs authorities to enforce the provisions of the Bill relating

to advertisements and to the disclosure of composition of medicines and to institute proceedings against contraventions. Sir FRANCIS FREMANTLE said he understood inspectors of the Pharmaceutical Society would be able to carry out duties which otherwise would fall upon a common informer. The clause was added to the Bill.

Sir ERNEST GRAHAM-LITTLE moved and, after discussion withdrew, a new clause which proposed to prohibit the sale under a fancy proprietary name of any preparation having essentially the same composition as preparations listed in current editions of the *B.P.* or the *B.P.C.*

On the Report stage of the Bill on July 22. Mr. ERNEST BROWN moved a new clause providing that it should be the duty of the Pharmaceutical Society to take all reasonable steps to enforce the provisions of Clauses 3, 4, and 6 of the Bill, and for that purpose the Society might employ the inspectors appointed by them under Section 25 of the principal Act.

Mr. Brown moved a series of amendments to Clause 6 (Disclosure of composition of medicines). He said he had examined very thoroughly disclosure in everyday terms and had decided that wherever a well-known term existed it should be used. He had fallen back on disclosure in terms which would be readily understood by a doctor, chemist, or any other expert. The amendments would require disclosure in one of the following ways: (1) Where a medicine or a constituent was a poison in the Poisons List the name to be used was that required in connexion with the labelling of the poison. (2) Where a medicine or a constituent was not a poison but was described in the *British Pharmacopoeia* or the *British Pharmaceutical Codex*, the description at the head of the relevant monograph must be used. (3) Where it was neither a poison nor described in the *Codex*, the accepted scientific name or other name descriptive of its true nature must be used.

So far as quantitative disclosure was concerned, the amendments required the quantities of the named constituents to be disclosed either by giving the percentages in the medicine or stating the actual amounts. When a medicine was supplied in the form of pills and tablets, disclosure might be made in one of three ways: (1) the percentage of the constituent in the medicine; (2) the quantity in each pill or tablet; or (3) the quantity of the constituent in the whole article. The effect of the amendments together would be to require disclosure in English.

Sir FRANCIS FREMANTLE and Prof. A. V. HILL welcomed the amendments, which were agreed to.

Miss HORSBRUGH, replying to Sir Thomas Moore, reiterated that there was no desire to prevent herbalists carrying on their work. With regard to faith healers, there was nothing in the Bill to stop treatment of any sort or kind, nor to prevent anyone treating anyone else for any illness. Neither a herbalist nor anyone else was stopped from making any mixture under a proprietary name and selling it under a proprietary name so long as there was disclosure as provided in Clause 6.

The Report stage being concluded, the Bill was read the third time. On July 23 it was read a first time in the House of Lords.

Red Cross Brassard

In the House of Commons on July 15 Mr. LAW informed Sir George Jeffreys that the Geneva Convention, 1929, provided that to claim the protection afforded by the convention to military medical services, personnel of voluntary societies such as the British Red Cross Society must be subject to military law. The only members of the British Red Cross Society entitled to wear the Geneva Cross armband were those incorporated with military medical units as determined by the Commander-in-Chief. Instructions were issued on this subject in March, 1940, and the position was subsequently made plain in correspondence with the British Red Cross Society in April of this year.

Women Doctors in the Services

Sir FRANCIS FREMANTLE asked on July 23 why women medical officers recruited to the Royal Air Force were not given the rank, status, and title accorded to male medical officers in the Service. Sir ARCHIBALD SINCLAIR said these women medical officers had the status of officers and the relative ranks pertaining to their duties and were addressed as medical officers. Sir FRANCIS said the title was not given. A woman medical officer was addressed

as "Miss Smith, Medical Officer." Sir ARCHIBALD SINCLAIR said special designations applied in the case of women's Services such as the Women's Auxiliary Air Force and the nursing services.

On the same date Sir VICTOR WARRENDER told Sir Francis Fremantle that only one woman medical officer was employed in the Navy. She held the relative rank of surgeon lieutenant R.N.V.R., received the pay of that rank, and wore the distinguishing stripes of a surgeon lieutenant on her sleeve. If women doctors were supplied to look after the W.R.N.S. personnel that would mean duplicating the medical staff and would lead to inefficiency. Only 2½% of the W.R.N.S. expressed a wish to have women doctors.

Gas and Oxygen by Midwives

Replying on July 24 to Dr. Summerskill, Mr. BROWN said that according to returns made by local supervising authorities up to December 31, 1940, forty-nine of the 188 authorities concerned had made arrangements approved by the Central Midwives Board for instructing midwives in the administration of analgesics. Apparatus for administering analgesics was supplied by thirty-three authorities during 1940 as compared with twenty-one during 1939. Under special arrangements made by the Ministry of Health with the National Birthday Trust, forty-three machines had been supplied to emergency maternity homes in which the staffs were adequately trained in the administration of gas and oxygen.

Examination and Discharge of Unfit Soldiers.—Captain MARGESSON, replying to Mr. Rhys Davies on July 22, said that existing instructions already provided that, as soon as it became doubtful in the opinion of the medical officer in charge of the case whether a soldier in hospital was likely to become fit again for further military service, that soldier was brought before a medical board so that a decision might be given without delay. All soldiers had to be brought before a medical board before the end of five months' continuous absence from duty, or three months in the case of patients in mental hospitals.

Doctors and Appeal to the Courts.—Mr. GROVES on July 22 asked the Lord President of the Council whether, having regard to the right of dentists, pharmacists, and certain other professional persons to appeal to the courts against disciplinary decisions, appropriate steps would be taken to amend the law and give doctors a similar right. Sir JOHN ANDERSON replied in the negative. He said that he was not satisfied that there was any general desire in the medical profession for such legislation at the present time.

Medical Services in Invasion.—Mr. Ernest Brown states that, in case of invasion, all local medical and first-aid facilities will be made equally available for both military and civilian casualties in areas which become the scene of actual operations.

Notes in Brief

A further Order under Defence Regulation 32 B is under consideration to include doctors resident in Great Britain who have obtained their degrees in Switzerland, Sweden, and other neutral countries.

Mr. Ernest Brown is in communication with Mr. Bevin about the rationing of materials used for occupational therapy in mental hospitals.

Mr. Bevin proposes to arrange that men who have been medically examined for the Armed Forces shall be informed that they should let the Ministry know if subsequently, while their calling-up is deferred, they think that their medical condition has deteriorated. A further medical examination may be held in such cases.

Mr. Brown has decided that the Nursing Division of the Ministry of Health, the establishment of which was announced on April 3, shall deal with midwifery as well as nursing. The Division will be known as the Division of Nursing and Midwifery.

Asked when he proposed to publish a summary report covering the work of the Ministry of Health, Mr. Ernest Brown said on July 3 that the material was being collated as rapidly as more urgent work permits. There would be no avoidable delay in the publication of the Summary for the two years 1939-40 and 1940-1. Mr. Ernest Bevin was unable to state what action would be possible to ensure the issue in an abbreviated form of the report for 1940 of the Chief Inspector of Factories.

The number of nurses employed in factories has largely increased of late. Three special short courses, at which trained nurses can receive supplementary instruction in industrial nursing, have so far been arranged by the Ministry of Labour.

A draft report has been revised, for publication at an early date, of the medical part of the investigation by the Medical Research Council of silicosis among coal miners. Environmental studies form the subject of a second report which is being prepared.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended July 5.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1941					1940 (Corresponding Week)

† Owing to evacuation schemes and other movements of population birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Infectious Diseases for the Week

Cerebrospinal and enteric fevers and pneumonia (primary and influenzal) increased in England and Wales during the week. In Scotland only enteric fever and diphtheria showed an increase, the former considerable, the latter very slight. In both countries acute poliomyelitis was more prevalent than last week, but the incidence remains low compared with last year and the year before.

Cerebrospinal Fever

During the six weeks ended July 5 notifications in England and Wales numbered 254, 244, 236, 211, 192, and 196 respectively. The disease is widespread, involving thirty-seven of the sixty-one administrative health areas in the country, but only in six were more than 10 cases notified during the week—namely: Lancaster 30 (Blackburn, Bolton, Bury, Crosby M.B., Droylsden, Fulwood, Kirkham, Litherland, and Warrington R.D. 1 each, Liverpool 4, Manchester 13, Salford 2, Clitheroe M.B. 2); York, West Riding, 27 (Bradford 2, Doncaster 1, Rotherham 4, Sheffield 8, Keighley M.B. and Kiveton Park R.D. 2 each, and York C.B., Castleford, Cudworth, Normanton, Otley, Shipley U.D., Hemsworth R.D., and Rotherham R.D. 1 each); London 15 (Fulham 3, Lambeth and St. Pancras 2 each, Bethnal Green, Camberwell, Poplar, Shoreditch, Stepney, Wandsworth, Westminster, and Woolwich 1 each); Warwick 12 (Birmingham 8, Coventry 3, Meriden R.D. 1); Glamorgan 12 (Cardiff 4, Merthyr Tydfil 1, Swansea 2, Bridgend U.D., Gelligaer U.D., Llwelher U.D., Neath R.D., and Pontardawe 1 each); Durham 11 (Gateshead 1, South Shields 2, Sunderland 4, Hetton, Ryton, Washington, Durham R.D. 1 each). In Scotland 300 cases were notified in the last six weeks, and in the first six months of the year 1,661, compared with 1,966 in the corresponding period of 1940. Eleven counties and eight burghs are at present involved, notably the counties of Ayr 6, Aberdeen 3, Fife 3, Lanark 3, and the burghs of Glasgow 15 and Edinburgh 4.

Enteric Fever

Of the total notified in England and Wales during the week, 46 more cases are of typhoid fever and the remainder of paratyphoid B fever. Nearly one-half of the total occurred in two areas, not more than 10 being notified in the other twenty-two areas for which notifications were received. The Birmingham and district outbreak of paratyphoid fever is declining, but cases continue to be notified in Stafford 47 (Stoke-on-Trent 40, Smethwick 1, Newcastle-under-Lyme M.B. 3, Tamworth M.B., Wednesbury M.B., Cheadle R.D. 1 each); Warwick 14 (Birmingham 10, Coventry 1, Solihull U.D. 2, Sutton Coldfield M.B. 1); Worcester 1 (in Kidderminster R.D.). Another area affected is Lancaster 35 (Blackpool 2, Bootle 7, Liverpool 21, Manchester 1, Southport 2, Morecambe and Heysham M.B. and Newton-le-Willows U.D. 1 each). In Scotland 6 cases of typhoid fever were reported (4 in Glasgow and 1 each in Ayr County and Arbroath burgh), and 37 cases of paratyphoid fever—namely: the counties of Angus 1, Fife 1, Lanark 5, Moray and Nairn 2, Roxburgh 2, and the burghs of Aberdeen 2, Dundee 17, Dunfermline 1, Glasgow 5, Edinburgh 1.

Diphtheria in Scotland

The unfavourable position in respect of diphtheria morbidity and mortality has led to a campaign which, it is hoped, will extend the benefits of immunization to children of pre-school age, even in rural districts. In two districts the medical officers of the clinic go round with a van to the remoter parts and have met with considerable success. During 1940 there were 15,711 cases and 676 deaths from diphtheria, compared with an average of approximately 10,000 cases and 410 deaths in the preceding four years; 50% of the deaths were in children between 1 and 5 years, and 83% between 1 and 10 years. So far 529,679 out of a child population of 1,124,500, or approximately 47%, (65% in school children and 30% in pre-school children), have been immunized; lower figures were recorded in urban areas.

Dr. Arnulfo Aras, a well-known practitioner in Panama, who had formerly been Minister of Health as well as Ambassador to Italy, has been elected President of the Republic of Panama.

Medical News

Not least among the pleasures we have to forgo in wartime are the anniversaries of learned and scientific societies. But for the war there would have been fitting celebrations last week of the centenary of the Reading Pathological Society, which was founded on July 13, 1841, and is thus the oldest pathological society in the country. The meetings of the society during these 100 years have been held without a break at the Royal Berkshire Hospital, with which the society has always been closely associated. In 1900 the Reading Medico-Chirurgical Society, which dated from 1824, was merged in the Pathological Society, and its library transferred to the rapidly growing one at the Royal Berkshire Hospital. For the last fifty years each new session of the society has been opened with an oration by a prominent member of the profession, and the list of orators contains many distinguished names. The centenary was marked by a commemorative service in the chapel of the hospital, the presentation to the society of the considerable reference library which had hitherto been the property of the hospital, and a centenary oration, "One Hundred Years in Retrospect," by Dr. G. O. Lambert, senior honorary physician to that institution.

Lieutenant-Colonel Henry Guest, M.P., presiding at the annual meeting of the London Chest Hospital, Victoria Park, E., said that despite very severe damage in recent air raids such good progress had been made in first-aid repairs that the hospital had now been reopened for in-patients and all departments had resumed working. A start had been made with the building of a new pathological department to replace the one that was completely destroyed, burying records and specimens representing ninety years of research on chest affections.

It is reported in the *Journal of the American Medical Association* that a blood donor centre has been organized in the Augusta-Victoria Hospital in Berlin.

The Trustees of the Dr. Jessie Macgregor Prize in Medical Science announce the award of the prize for the present triennial period to Miss Agnes Rose Macgregor, M.D., F.R.C.P.Ed., for her work on pneumonia in the newborn. The prize is open to medical women who are graduates in medicine of the University of Edinburgh or who have taken the triple qualification of the Scottish Medical Corporations. It is awarded to the applicant who presents the best record of original work in the science of medicine during the past three years, and is of the value of £75.

A certificate presented to Parliament by the Prime Minister enables Prof. A. V. Hill, Sc.D., F.R.S., who has become an Associate Member of the Ordnance Board, to retain his seat in the House of Commons as one of the Members for Cambridge University.

The names of Mr. Charles Alfred Keogh, F.R.C.S., surgeon, London, and Dr. Alexander Hendry MacKie, medical practitioner, Birmingham, have been brought to notice for brave conduct in civil defence.

Dr. Kenneth R. Hay and Mr. H. S. Souttar have been elected Managers and Dr. Russell J. Reynolds a Visitor of the Royal Institution.

Sir John Boyd Orr, M.D., F.R.S., Director of the Rowett Research Institute, has been re-elected president of the Aberdeen branch of the Children's Nutrition Council.

A Pan-American League against Cancer has been founded in New York under the presidency of Professor Angel H. Roffo, director of the Institute for Experimental Medicine in Buenos Aires.

At Baltimore the Public Health Service maintains a tumour clinic which serves as a demonstration of the life-saving possibilities of adequate cancer treatment. In the first eight months of its existence 226 patients were treated.

Switzerland will celebrate the 400th anniversary of the death of Paracelsus at Einsiedeln from September 27 to 29.

Professorships of industrial hygiene have been established at Turin, Sienna, and Padua, so that with those at Milan and Naples Italy now possesses five such chairs.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS of their articles must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be addressed to the Secretary.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES—EDITOR, *Aitiology Westcent*, London; SECRETARY, *Medisecra Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Income Tax

Change from Employment to General Practice

"J. G. M." was employed as an assistant up to the end of April, 1941, earned £28 as a locumtenent in May, and has since started in general practice. He is still being asked to pay tax on his employment earnings.

* The tax payable on the salary as assistant for the year to April 5, 1941, would normally be deducted in equal monthly amounts over the period November 1, 1940, to October 31, 1941. Presumably when "J. G. M." left his employment at the end of April there would be some tax not then due for deduction, and therefore not paid. He is liable to account directly to the Revenue for that balance of his liability for 1940-1. In addition, of course, he will ultimately have to account for the liability (if any) on his earnings of April, 1941, as part of his income for 1941-2.

Appointment: Car Allowance

"F." holds a full-time appointment as M.O.H. and receives a car allowance of £100. This amount is inadequate in war conditions, but the inspector of taxes refuses to make a deduction for the excess expenditure.

* The rule applicable to Schedule E is strict—expenses to be allowable must be "incurred wholly, exclusively, and necessarily in the performance of the duties of the office." The inspector presumably takes his stand on the assumption that whatever amount "F." in fact expends, the appointing authority have made an allowance on the basis that £100 covers necessary expenditure, and we think that in the absence of other evidence that is likely to be the view taken on appeal to the local commissioners. Possibly "F." could obtain a statement from his authority that while they are unable to increase the allowance they no longer regard it as adequate to cover necessary expenditure. That would be very helpful evidence in support of his claims.

Reduction in Practice Income

"HARD HIT" has a partnership in a practice which has suffered severely owing to the war, with the result that the previous year's basis works harshly.

* If—as is apparently the case—"Hard Hit's" earned income calculated on the basis of the actual year is not more than four-fifths of the earned income as assessed he can claim to have his liability adjusted to the actual year's basis. An application should be made to the Inspector of Taxes accordingly, and should be made by each individual partner and not by the firm as such. As regards the current financial year, tax will not be payable until January, 1942, and if the necessary accounts are not then available no doubt some arrangement can be made for the acceptance of a payment on account.

Dominion Income Tax Relief

"A. T." has income from a Dominion on which £10 10s. income tax is paid there. He has been refunded £7 by the British Government, but this £7 is being taxed as income.

* Prior to the introduction of this relief the tax paid in the Dominion was regarded as deductible in calculating the liability to British income tax—i.e., "A. T." would have been assessed on, say, £100—£10=£90 in full. The present position is that relief can be claimed in respect of the Dominion tax up to a maximum determined by half the "appropriate rate" of British tax payable by the claimant. In so far as this relief reduces the amount suffered by payment of Dominion tax, that tax ceases to be

deductible in calculating the amount of the income for assessment to British tax. The relief as suggested above does not extend in many cases to the whole of the Dominion tax; if it did there would be no inducement for reciprocal action on the part of the Dominion concerned.

Reduction in Civil Earnings

"MILES" is serving in the Forces, his practice being run by a locumtenent. Can he claim to deduct the whole of such expenses as maid's wages and upkeep, gas, light, and telephone?

* In the circumstances it seems reasonable that a higher proportion than formerly should be claimed and allowed, but so long as a part of the premises is not being used for professional purposes—the rooms occupied by the locumtenent being regarded, however, as used professionally—"Miles" will be unable to enforce a claim to allowance of the whole of such costs. If the actual total income of "Miles" for 1940-1 is not more than four-fifths of his earned income for that year he can claim to have the assessments adjusted to the actual basis.

LETTERS, NOTES, ETC.

Treatment of Cracked Finger-tips

Dr. M. R. SONI (Manchester) writes: Cracked finger-tips are very common in winter. Persons with soft skins who have not done any manual work and who are new to war work suffer especially from this painful condition. As a preventive and curative measure elastoplast should be applied in the following manner after cleansing the hand thoroughly with grease-solvent soap and paring the edges of the crack with a safety-razor blade. Cut the plaster in the manner illustrated below:

Place the tip of the finger (beyond the distal joint) along the side AB in its centre. Bring down EF over the finger-tip and the nail and stick it to the dorsal surface. Pull on the sides AC and BD and press their adhesive surfaces together in the middle line. Cut off all redundant plaster and mould the dressing to the form of a thimble. In this manner elastoplast makes a neat little dressing for the finger-tip which need not be disturbed for a few days. I have known patients to do work of a delicate nature wearing "thimbles" on all the finger-tips. The dressings stand wear and tear, and are to some extent waterproof. If the surface of the skin is broken a little plain zinc ointment should be applied to the wound on a small piece of lint before covering it up with plaster. As a corrective measure a little "HEB" (protective) should be rubbed into the hands night and morning. This preparation is manufactured by J. Halden and Co., Ltd., of 37, Brazenose Street, Manchester, according to the formula of Dr. P. B. Mumford (see *British Medical Journal*, February 11, 1939, p. 266.).

Attending a Colleague

"SCOTIA" writes: In a recent issue of the *Journal* a suggestion was made as to how medical practitioners could repay specialists for their attendance on them. I would suggest that every doctor voluntarily should pay £1 ls. annual subscription for himself and an additional £1 ls. for his wife and children into a general fund, which would amount to many thousands a year. From this specialists should be paid a standard but not reduced amount, and this would make it easier for the general practitioner to approach the already too willing specialists. Each hospital could provide a room for the use of the patient; the hospital would be paid the usual private room fees from the fund. The medical profession as a whole are not often patients and not for longer than is necessary, so that eventually from the same subscription a sickness insurance might be possible. This insurance should be entirely in the hands of the profession to avoid unnecessary expenses.

Minerals and Vitamins in a "Health Dinner"

In a bulletin issued by Vitamins Ltd. (which can be obtained on application to the firm at 26, Upper Mall, London, W.6) the following food values are given for a modified "Oslo breakfast" recently given to a group of London school children as a "health dinner."

	Vit. A Units	Vit. B, Units	Vit. C Units	Vit. D Units	Available Iron mg.	Calorie mg.
Salad: lettuce 1 oz. . .	934	6	62	—	0.10	70
tomato 1 oz. . .	844	7	138	—	0.03	10

Roughage in Food

Dr. JOSIAH OLDFIELD writes: I think the medical profession should set their faces against the word "roughage," which has been introduced of late years by writers on dietary. It gives a wholly unscientific view of the processes of digestion, assimilation, and defaecation. "Roughage" gives the idea that the alimentary canal works by a process of irritation, and anyone who uses the word thinks of it as something which scrapes along. This fallacy has made the fortunes of patent medicine vendors, because owing to the conditions of modern life constipation is one of the commonest ailments of humanity. The majority of patented medicines, and even of prescriptions given by the medical profession, are based upon the use of either vegetable or mineral irritants. Study of digestion teaches that this is an entirely fallacious method of looking at the physiological processes which accompany the intake of food and the excretion of waste matters. In a cow (which is one of the best illustrations I know of an animal that never suffers from constipation), the contents of the second stomach after the chewing of the cud could never, by any stretch of language, be called "roughage," and yet those who have ever kept cows would admit that there is no animal they know in which the digestion is so easy and certain. The alimentary canal works on the harmonious relation between the muscular structure of the intestinal walls and the contents of the intestine. This relation is not one of irritation but entirely the reverse. The human animal should always be in a state where the contents of the alimentary canal afford the soothing stimulus and the necessary mass for the musculature of the walls to function upon. We find as an experience that when men live upon "the kindly fruits of the earth" constipation is unknown. It is not the coarse corn and the modern foods made of bran which are the harmonious foods, but the admixture of vegetables of the garden, fruits of the orchard, grains of the harvest field, and oils and fats of the nut tribes which will always provide a suitable bulk, a suitable stimulant, and a suitable mass for muscular action. To these foods may be added products of the dairy, such as milk and cheese, and eggs, though these are all comparatively constipating; but no constipation can ever persist where the food consists largely of the products of the earth.

Skin and Mind

Dr. E. SAKOSCHANSKY (Southampton) writes: I have read your annotation on skin and mind (July 12, p. 55). In my opinion there is no need for such apologetics as "apt to begin with confusion and end with incredulity" or "avoid the role of obstructionist," etc. After all, the brain is derived from the skin: it is no more than an invagination of an especially sensitive part of the skin. Both the brain and the skin are rich in cholesterol; therefore both probably react in a similar way to certain metabolites and ions. Hence it follows that the "frequent association of certain allergic phenomena with a particular type of personality" may be due to a similar make-up in the skin and in the brain.

Accommodation for Doctor's Child

Dr. X. Y., who practises in a small country town in the Cotswolds, offers accommodation to a doctor's child, preferably a girl between 3 and 5 years of age, from a "blitzed" area. Dr. X. Y. has two children, a girl of 4 and a boy of 2. Accommodation is offered, in return for actual expenses only, either for the summer or for the duration of the war. Letters addressed to Dr. X. Y., c/o the Editor, will be forwarded.

LONDON SATURDAY AUGUST 9 1941

THE MENTAL DEFECTIVE IN THE ARMY*

BY

F. J. S. ESHER, M.B., Ch.B., M.R.C.S., L.R.C.P., D.P.M.

Medical Officer in Charge, Mental Deficiency Department, Sheffield Corporation; Assistant Lecturer in Mental Diseases, Sheffield University; E.M.S. Psychiatrist

It is vital to success in military operations that commanding officers should know the limitations and weaknesses of the units they employ no less than their numerical and physical strength. Mental defectives constitute such a point of weakness, a matter which is the more important because it is often not recognized till too late. This paper discusses the evidence that mental defectives are a hindrance to a modern army, easy and quick methods of detecting them, and recommendations for removing the more serious cases of defect at an early stage.

The Defective a Hindrance to the Unit

The mental defective differs from the normal person in that he is less able to meet new situations, is backward in learning, has less foresight and therefore does not appreciate the risks he is bringing on himself and others, has less initiative, and is slower in thought and action. In the Army of to-day, in which complicated machines are increasingly used, speed in action is essential both to success in battle and to the safety of the unit; the soldier must have more initiative and a better understanding of technical apparatus than were needed in former wars. The bow-and-arrow was simpler than the flintlock, which is a toy beside the machine-gun. The mental defective who can only master the rifle is at a disadvantage compared with those who can handle, clean, and maintain more complicated weapons, and he cannot in an emergency give them enough support.

Mental defectives are slow learners, and therefore hold back the training of normal men. The lower the mental age the more difficult they are to train. In my experience all those of a mental age of up to 7 years 11 months are untrainable; 86% of those with a mental age of 8 years, 58% of 9 years, 33% of 10 years, 28% of 11 years (see Chart).

Case A.—This man was notified by the National Service Recruiting Board to be "slow mentally and illiterate"; on account of this he was placed in Grade II. As he was untrainable he was sent to me for examination six months after joining up. His mental age was 5½ years. He told me he had been a sentry for five months. When asked about this, he said that he couldn't fire a gun and was generally terrified of being left alone in the dark. He had been put to guarding a gun site. In peacetime he could practically get no work. He had held two jobs in seventeen and a half years, and had been out of employment for fifteen years of this time.

Case B.—A man in the Royal Engineers was frequently crimed for petty offences, such as changing his billet without permission, arriving late on duty, etc. He seemed unable to realize that he had broken regulations, though he had been in the Forces for eighteen months; it was apparently impossible to train him as a soldier. His mental age was 6 years.

Case C.—This man wept copiously as soon as we began to talk. His medical officer said he was asocial and was shunned by

his comrades. He was untrainable after five months in the Army and was useless even for fatigues. He was very worried about leaving his six children, as his wife was going to have another soon. He was illiterate, and his mental age was 4½. He did not know whom the war was against—in fact, he was not aware that there was a war on.

It would not have been difficult to discern that these men would never make soldiers if those responsible for their acceptance had been aware that mental deficiency was a definite hindrance to military efficiency.

The mental defective unable to cope with his new environment is more prone to report sick for small and varied ailments. In a series of 100 cases sent to me for examination for mental deficiency 42% were chronically sick. Most were not seriously or even moderately ill.

Case D.—A man aged 23, six months in the Royal Artillery, complained of pains in the feet and of inability to march or drill. He had been to an orthopaedic specialist, who could find no reason for the pains, but reported that he had double pes cavus; spectacles, which he said did not suit him, had been provided, and he had been to a dermatologist for ichthyosis. He had had his appendix removed in a general hospital, and later it was found that there was sugar in his urine. He had attended an open-air school and was physically frail. The N.S.R.B. placed him in Grade II. During performance tests he was described as a "lethargic twiddler," and on the Terman test he had a mental age of 9½ years. His physical and mental conditions were degenerate and under-developed. Most of his six months of Army life had been "under the doctor."

R.M.O.s commonly report that it is the dull, inefficient soldiers who turn up most regularly at sick parades, that many of their ailments are quite trivial, and that "the defectives use their illness to get out of their difficulties." It would perhaps throw a broader light on the problem to say that when the defective is bewildered in his new environment his attention turns to his own bodily sensations, rather hypochondriacally, in the hope that the M.O. will supply a comforting bottle of medicine and suspend him from perplexing duty. If at the same time he is ordered to the sick bay then so much the better: for many defectives, when children, needed and received more parental care than normal youngsters. Being nursed is something they both know and enjoy. Such behaviour, however, lowers the morale of the unit and rouses resentment among those who are also struggling to adapt themselves to their new environment and to hold back their personal claims and troubles in the common struggle of war.

To frequent illness we may add clumsiness. A sergeant-instructor told me that it was the 20% whom he found most difficult to teach to drive who had the most accidents. Allowing for a few "accident-prone" (who are not always hard to teach), many of these slow learners and clumsy drivers were probably defectives.

* Based on a paper read to a meeting of the British Psychological Society at Nottingham, April 19, 1941.

Sample of Military Defectives

In a series of 100 mentally defective soldiers seen consecutively, 80% had mental ages of from 9 to 11, and 14% of from 5 to 8 years (see Chart). This distribution is not typical of the scatter of mental defectives in the population. It would be satisfactory to believe that the low- and medium-grade feeble-minded had been kept out by the recruiting boards; but that they are kept out is more probably due to the working of the Mental Deficiency Acts, 1913-38, for the majority of those whose mental age is 8 or less cannot support themselves at all and are in institutions, on licence, under guardianship, or notified to the local mental deficiency authority, and are therefore exempt under the National Service (Armed Forces) Act, 1939, Section 11 (f).

It will be noted that while more men with mental ages of 9 and 10 were useless to the Army than those with mental ages of 11 and 12, yet there are fewer of them in the general population. These men of 11 and 12 mental age are "military defectives" even more than they are "civilian defectives," since they cannot adapt themselves to such new and complicated duties as a modern army requires them to perform. In civilian life they could choose their occupations; if unable to do their allotted tasks they did not thereby endanger the lives of their companions and would change to work which was more congenial, and which gave them a sense of achievement rather than of frustration.

The above-mentioned 100 men were asked to furnish particulars of their various employments and the time they worked on them. From these times was compiled the following table, to which unemployment time has been added.

	Years		Years
Out of work	241	Shop assistants	46
General labouring	193	Delivery (mainly coal and milk roundsmen)	30
Coal-mining	153	Army and Navy Regulars	23
Machine feeding	104	Hand-truck pushers	24
Pedlar; hawk	74	Window-cleaning	17
Painter	73	Other occupations	91
Farm-hand	71		
Odd jobs (unemployed about 50% of time)	60		
Totals: Employment 959 years; Unemployment, 241 years.			

Counting their potential working time as 1,200 years, these 100 men had been out of work about 20% of this—i.e., 241 years. It might engage the curiosity of M.O.s of units to find out whether their mental defectives do not spend a like proportion of their time in the Army on the sick list. The above list does not indicate the character of the work actually done—in the coal-mines, for instance, the men are mainly employed on the less skilled jobs—but it does show how they are occupied in a free market. In the Army, where duties are allotted and have to be carried out without much time for instruction, the defectives break down on the job. Men who are of so little use to the community in time of peace should not be allowed to hinder an army during wartime.

Analysing the reasons why these 100 men were sent for a psychiatric opinion, it was found that 50% were regarded by their M.O. or C.O. as untrainable; 25% were apparently stable before enlistment but broke down and were sent to hospital suffering from a psychiatric complaint which manifested itself after enlistment, the commonest symptoms being those of conversion hysteria and anxiety; 43% were unstable before enlistment; and their discharge was recommended on grounds of continued temperamental instability; 42% were regularly reporting sick or had some psychoneurotic ailment—i.e., over a half of them had more than one of these reasons for being sent for investigation.

In the light of the above figures it will not be a surprise that in an investigation of 904 consecutive cases admitted

to a special centre for neurosis and measured by the progressive matrices 33% came from the lowest 10% taken into the Army. This would suggest that one way of re-

Graph showing proportion of mentally defective soldiers breaking down, sick, unstable, or untrainable at various mental ages (100 cases).

ducing the incidence of neurosis in the Army is to keep out the mental defectives, who, though in a minority numerically, constitute a major problem.

Duration of Service before Mental Defect is Detected

When we remember that mental defectives by their slow-wittedness hinder the training of normal men and break down easily themselves, we become curious regarding the time that elapses before their defect is detected or it is realized that, in spite of painstaking endeavour, they may be untrainable. It may therefore be instructive to examine the following table showing the length of Army service of 100 mentally defective soldiers sent for examination.

Under 1 week	1	9-12 months	7
1-2 weeks	6	12-15	5
2-4	4	15-18	3
1-3 months	19	18-24	3
3-6	26	Over 2 years	4
6-9	22	(3, 4, 4½, 5½ years)	

These figures should be examined in relation to the stages of training. Though the work is relatively easy in the first three months, 30% showed clearly that they could not stay the course. During the next six months the soldier has to learn to handle more complicated weapons and to carry out military exercises which call for a greater amount of self-reliance in the face of complexity and uncertainty. It is therefore not surprising that 78% of the defectives examined had failed before they were ready for active service.

Aids in Spotting the Defective

The defective has, on the whole, a different school and work history from that of the normal soldier. Though no one would diagnose a defective on that history alone, the following points will help those who are uncertain whether to send a given case for an opinion to the psychiatrist attached to the recruiting boards or, if already enlisted, to the Command or E.M.S. psychiatrist.

There is generally one standard (form, class) for each year of the child's elementary-school life (7 to 13 years), corresponding with Standards I to VII. In the past, and therefore affecting the older soldiers, boys went up to a higher standard only if they passed the necessary test. Therefore when we find that a soldier did not reach one of the top three standards we may suspect mental defect.

In more recent years there has been a general tendency to avoid the inclusion in the same form of larger or older children among those who are less mature; the aim was to prevent deterioration of character and development

through the temptation to bully the younger ones. This was accomplished in two ways. In one the child was promoted yearly, and therefore left the school in the top standard. Defective soldiers educated on this principle will often admit that they were unable to keep up with their fellows and were therefore at the bottom of the class, or that their promotion was due to their age or size and not to their abilities. In the second way the schools were organized along the lines suggested by the Hadow Report—Standards V, VI, and VII being called Forms I, II, and III. These forms were subdivided into "streams" A, B, and C (also D in larger schools, only A and B in smaller). These "streams" generally represent ability: the dull children go in the C stream (and D in the larger schools) and the cleverer in the A stream. Exceptionally, the forms are subdivided according to the type of work done—e.g., A: commercial; B: technical (trades), etc.; so that dull and clever "commercials" would be in Form IIIA, and the B stream would include boys with, say, high mechanical ability.

Illiterate soldiers, and those very nearly so, are almost invariably mentally defective, unless there is clear reason for illiteracy—e.g., lack of schooling; those who attended special schools are generally defective from a military standpoint, and many who went to open-air schools are dull and defective (or, if not, should have special investigation on grounds of doubtful physical health). Soldiers from secondary or technical schools and colleges are unlikely to be mentally defective unless they were fee-paying scholars in a school without an entrance examination, when they may be defective.

The following table shows the standards from which 100 mentally defective soldiers left school compared with those from which 100 psychoneurotic soldiers left. It shows that of those who left in Standard IV or lower 5.3 : 1 (32 : 6) and of those from Standard V or lower 3.4 : 1 (54 : 16) were mentally defective.

	100 Mental Defectives	100 Psychoneurotics
Standard II	3	7
III	13	5
IV	17	10
V (or Form I)	22	16
VI (or Form II)	19	27
VII (or Form III)	12	29
VIII (or Ex-VII)	5	18
No schooling	5	7
Didn't know	3	2
Schools with unorthodox class numbering	3	7
College	1	1

Work Histories

Mental defectives often show characteristic features in their work histories.

(a) *Employability.*—The more defective a man the less likely is it that he can be employed usefully; therefore among those with long periods of unemployment will be found large numbers of mental defectives. Unless the nature of his work or local or other conditions are the cause, a period of unemployment of over three years at any time in a fit man's career should lead to a suspicion of mental deficiency or other mental trouble. If his unemployed time exceeds his employed time the same suspicion should be held.

(b) *Unrequerative Work.*—Defectives will often work for a wage that a normal man would regard as too low a one on which to live. Wages of £1 a week or less in the country or £1 10s. or less in town, or keep and 10s. or less in town, or 5s. or less in the country, would come into this category.

(c) *Types of Occupation.*—Certain types are favoured by defectives; they include such as: Ice-cream vendor, sandwich-man, handing round bills, odd-job man, newspaper vendor (street-corner), rag-and-bone man, door minder, scrap metal collector, tea masher, errand man, street sweeper or sweep-up in works, cinema attendant (outside). The holding of any one of these jobs

does not in itself constitute a pointer to mental deficiency or to mental disorder, but if a man holds a succession of them and does not rise above them though employment is available, or if he sinks to these levels after holding better posts for brief periods, then mental defect should be suspected.

Since these pointers are not aids to diagnosis, it is immaterial at this stage whether they indicate mental defect, severe neurosis, or mental degeneration: the differential diagnosis introduces other factors which need not be discussed here. It may also be noted that the pointers may be used by physicians who have not had special experience in mental deficiency, or even by their clerks.

American Experience

The problem of mental deficiency among soldiers is not new to military medicine, though it is sometimes neglected. During the war of 1914-18 the American Army introduced intelligence tests at the registration of recruits. The standard for rejection was "a mentality not exceeding that of a child aged 8 years"; for it was considered that below this level the "degree of incompetency was so profound that the individual, whatever his race or surroundings, could not be counted on to take care of himself." In spite of so low a standard, 1.2% of all men registered were prevented from joining that Army on grounds of mental defect. As a result of these tests only 0.2% of men admitted into the Army had to be discharged later as defectives because of their inability to train into useful soldiers. If the distribution of intelligence in America is comparable to ours in Great Britain the rejection of 1.4% for mental deficiency suggests that the Army in fact considered as defective men with a higher level of intelligence than 8 mental age years—perhaps 9 years. The increased use of mechanized units, and the necessity for speed of action and co-operation between scattered formations, leads me to conclude that in the majority of cases a mental age of 11 or less makes a man unfit to play a useful part in a fighting unit.

It would certainly, in the long run, prove an economy of effort to institute tests for intelligence during the recruiting examination of all persons. As such are not yet provided, the hints given above may prove of assistance.

Where the Defective is Useful

Much has been said about the defective's hindrance to efficiency; about his constituting a risk, his waste of Army time and equipment, and his clumsiness; and about turning or keeping him out: all this, while true, should not obscure the fact that, of 1,200 years which the 100 men might have worked, they did, in fact, between them put in 959 of gainful if fitful toil. Because they are mentally defective they cannot adapt themselves to new situations or acquire skill in fresh directions, but they can often do simple repetitive work and fill "blind-alley" jobs without hurt to their pride, and without boredom or injury to their ambition. It would therefore seem prudent in the national interest to put these men to such tasks as they can fulfil in civil life, where their defect will prove less of a hindrance.

According to the wording of the Registration for Employment Order, 1941, those exempted from the need to register for military service under the National Service (Armed Forces) Act, Section 11 (f)—such as notified mental defectives—are also exempt from registering under that Order. This arrangement makes it difficult for such men as are notified to the local mental deficiency authority to do work of national importance that may well be within their capabilities. If this Order were amended men unfit to be soldiers yet fit to do labouring or machine-feeding in a munition works could make their contribution to the national effort.

Recommendations

1. Those with a mental age of less than 10 years should be prevented at the recruiting boards from joining the Army or, if already enlisted, should be discharged.
2. Since those with mental ages between 10 and 12 are often unstable, break down more than the normal under active service conditions, and frequently report sick, they should be sent to a labour corps and receive special consideration at the end of three months' service. Due allowance for a fall in intelligence due to age should be made in the case of older soldiers (I allow a drop of 1 year of mental age for each decade after 25 years in computing the mean score for average older men).
3. To arrive at a rough assessment of the mental age the progressive matrices tests could be used; but the method of assessment is not so important, though there are several reasonably reliable methods. What is really important is that some systematic attempt should be made to eliminate the defectives.
4. Since some people will raise an objection to the idea of "weeding out" defectives it should always be stressed that the task is to keep certain less gifted members of the population at jobs in which they are stable and in which they can be of most use to the national effort.

Summary

The mental defective in the Army—slow to learn, prone to breakdown, a misfit and potential danger—is discussed. Aids in spotting the defective are given. It is pointed out that, though a hindrance in the Army, he may be put to useful work in civil life in wartime. Recommendations are made for handling the problem.

I wish to express my thanks to Dr. John Rickman for advice in the preparation of this paper.

HYPOPROTHROMBINAEMIA AND AVITAMINOSIS-K IN MAN

BY

ROBERT KARK, B.A., M.R.C.P.

AND

ALEXANDER W. SOUTER, M.B., Ch.B.

(From the Thorndike Memorial Laboratory Second and Fourth Medical Services (Harvard) of the Boston City Hospital, and the Department of Medicine, Harvard Medical School)

The control of haemorrhage in man is dependent on the "protective" reaction of the vascular tree to trauma and on the ability of the blood to coagulate normally. Although the former defence mechanism is not at all clearly understood, recent studies have demonstrated the validity of the so-called classical theory of blood coagulation (Eagle, 1939), and the majority of workers in this field now subscribe to Schmidt's (1895) original hypothesis, concisely expressed by the following equations:

Despite the fact that very little is known of the chemical nature of any of the organic constituents of the plasma, which react together to form a blood clot, clinical and experimental studies by chemists, biologists, and physicians during the past five years have provided a sound basis for the diagnosis and treatment of previously obscure haemorrhagic diseases. This advance in knowledge is in the first place due to the recent development of methods for the estimation of blood-prothrombin levels (Quick and others, 1935; Brinkhous and others, 1938; Dam and Glavind,

1938), which are more specific than those previously used (Howell, 1914); and, secondly, because Dam and his co-workers in Copenhagen were able to demonstrate that a fat-soluble substance, vitamin K, could restore the marked hyperprothrombinaemia and control the haemorrhagic tendency of experimental dietary "haemophilia" in chickens (Dam and others, 1936).

It is the purpose of this communication to discuss some of the clinical aspects of hypoprothrombinaemia and avitaminosis-K in man in the light of recent knowledge and as a result of personal observation of 178 patients in the Boston City Hospital during the past two years. The majority of these patients suffered from haemorrhagic manifestations and all were suspected of having a diminished blood-prothrombin concentration. Consequently their blood-prothrombin concentration levels were measured by

FIG. 1.—The relation between the prothrombin percentage of human plasma and the Quick prothrombin time in the presence of excess tissue thromboplastin, giving a Quick prothrombin time of 25 seconds for normal control plasma.

Quick's method. The test measures the time taken for a sample of citrated plasma to coagulate, after recalcification, in the presence of an excess of tissue thromboplastin, as compared with the time taken for a sample of normal citrated plasma to clot when treated in the same way. Conversion of these "times" to blood-prothrombin concentration are made by reference to a curve (Fig. 1) constructed according to the method of Kark and Lozner (1939).

The Quick test is extremely simple, and the recent introduction of a stable thromboplastin (Souter and Kark, 1940), requiring only the addition of distilled water before use, would seem to remove the one serious obstacle to the performance of the test in the physician's office, and also enables it to be performed with greater ease elsewhere. The Quick test is performed as follows:

4.5 c.cm. of blood is taken into a saline-washed syringe by means of a clean venepuncture, and mixed with 0.5 c.cm. of 2.5% solution of sodium citrate in a centrifuge tube. The blood is spun at 1,500 r.p.m. for five minutes and the plasma drawn off. The test must be performed on this plasma within the next six hours.

Thromboplastin is prepared by stripping the brain of a freshly killed rabbit of blood vessels and meninges and washing it in tap-water. The brain is then macerated, spread thinly on plate-glass, and dried in an oven at 37° C. for twenty-four to forty-eight hours. To each 0.5 gramme of this dried material 5 c.cm. of a 0.85% solution of sodium chloride is slowly added and thoroughly mixed into a thin paste. The paste is incubated for fifteen minutes in a water-bath at 56° C. and then centrifuged at 2,000 r.p.m. for five minutes. The upper layer of opalescent fluid in the centrifuge tube is used as a source of thromboplastin and retains its activity for from two to four days when kept in the ice-box.

To perform the test, 0.1 c.cm. of thromboplastin solution is pipetted into a 75 by 19 mm. tube, together with 0.1 c.cm. of plasma; such a clot forms within twenty to twenty-five seconds. Chloride solution, containing 0.277 gramme of calcium chloride per 100 c.cm. distilled water, is then added. The stop-watch is started and the tube is agitated for fifteen seconds in the water-bath. The tube is then removed from the water-bath and tilted gently up and down once or twice a second. The end-point is sharp, and occurs when the mixture suddenly ceases to flow smoothly and a clot is formed. In normal plasma such a clot forms within twenty to twenty-five seconds, depending on the batch of thromboplastin used.

It is extremely important to check each new thromboplastin solution against a normal control plasma before making observations on the plasma of patients suspected of having hypoprothrombinaemia.

Clinical Manifestations of Hypoprothrombinaemia in Man

A haemorrhagic state consequent on a reduction of active prothrombin in the circulating blood does not arise unless the blood-prothrombin level has dropped considerably. Although there is a wide margin of safety, personal observations indicate that the critical level for bleeding is somewhat higher than the 15 to 20% of normal which Quick (1938) originally postulated.

Of the 178 patients studied 53 had a haemorrhagic condition which was directly consequent on a marked hypoprothrombinaemia and which, in most instances, was controlled by vitamin K therapy. This condition, which we have termed haemorrhagic hyperprothrombinaemia (Kark and others, 1940), may be divided into two classes—latent haemorrhagic hypoprothrombinaemia and spontaneous haemorrhagic hypoprothrombinaemia.

Latent Haemorrhagic Hypoprothrombinaemia

When the patient's blood-prothrombin level has fallen to about 35% of normal, haemorrhagic manifestations occur at the sites of obvious trauma; bleeding starts from recent operation wounds or where the gums have been damaged by too vigorous brushing of the teeth. Below this level, too, dangerous haemorrhage occurs from intestinal ulcerations, if they are present. One physical sign especially gives evidence of the marked reduction in the blood prothrombin. In all patients in whom the prothrombin level had dropped to below 35% of normal, haematomata became evident at the site of venepuncture or where the skin had been punctured for bleeding-time estimations. These "needle-puncture haematomata" were often the only outward clinical evidence of a dangerous tendency to bleed.

Spontaneous Haemorrhagic Hypoprothrombinaemia

A spontaneous haemorrhagic diathesis becomes apparent when the blood-prothrombin level has fallen to from 15 to 20% of normal. This condition is seen especially in newborn infants and occasionally in patients suffering from idiopathic steatorrhoea (Kark and others, 1940), obstructive jaundice, or severe parenchymatous hepatic disease.

The condition may manifest itself by the spontaneous appearance of large haematomata on the back, thighs, or other sites of pressure. Dramatically, haemarthrosis, severe haematemesis, epistaxis, haematuria, or melaena may be the presenting symptom. Menorrhagia and intracranial and retinal haemorrhages have been noted. Intractable haemorrhage may occur from trivial skin wounds or, in infants, from the umbilical cord. Although the gums may bleed they do not show the purple sponginess characteristic of scurvy, and perifollicular haemorrhages of the skin are not a feature of this condition. Laboratory studies are striking. The blood-coagulation time is prolonged, but not to the same extent as it may be in haemophilia. No abnormalities are noted in clot retraction either in clotted whole blood or in recalcified plasma. The bleeding time, though usually

normal, is occasionally prolonged.* The capillary fragility is unaltered, as is the blood-platelet count. Marked prolongation of Quick's prothrombin time is present, and is the crucial finding.

The main features of haemorrhagic hypoprothrombinaemia are as follows:

"Needle-puncture" haematomata; continued and prolonged wound haemorrhage; subcutaneous haematomata, especially at pressure points; haemarthroses, epistaxis, haematemesis, melaena, haematuria, retinal haemorrhages, menorrhagia. No gum changes; no perifollicular haemorrhages.

Laboratory Data.—Blood—prothrombin concentration markedly reduced; prolonged coagulation time; occasionally increased bleeding time; normal capillary fragility; clot retraction normal; platelets normal.

Clinical Causes of Hypoprothrombinaemia in Man

The development of hypoprothrombinaemia in man is usually associated with evidence of florid pathological disturbances of the bile ducts, intestine, or liver. Although the precise interrelationship between these organs, vitamin K, and prothrombin is not understood, the broad outlines of the physiological processes which maintain an adequate concentration of prothrombin in the blood have been clearly drawn. Experimental evidence has shown that prothrombin is formed by the liver (Smith and others, 1937; Warren and Rhoads, 1939) if an adequate supply of vitamin K is maintained. Furthermore, the presence of bile salts in the intestinal canal is necessary for the proper absorption of the naturally occurring vitamin, which is an oily substance (Greaves and Schmidt, 1937; Greaves, 1939). Prothrombin is destroyed in the body by passage through the lung (Andrus and others, 1940) and perhaps by a sustained rise in temperature (Wilson, 1939). Thus it is clear that hypoprothrombinaemia may develop as a result of a nutritional deficiency of vitamin K or following a disturbance in the formation or metabolism of prothrombin.

With this in mind the following classification of diseases in which hypoprothrombinaemia is known to occur is suggested:

NUTRITIONAL DEFICIENCY OF VITAMIN K

Restricted or Unbalanced Diet.—Scurvy; pellagra; rickets; idiopathic steatorrhoea; haemorrhagic disease of the newborn.

Defective Absorption from the Intestine.—(1) In the absence of bile salts: Obstructive jaundice; biliary fistula. (2) In the presence of intestinal disease: Regional ileitis; ulcerative colitis; intestinal obstruction: polyposis coli; idiopathic steatorrhoea; neoplasm of the intestine.

METABOLIC DISTURBANCES OF PROTHROMBIN ANABOLISM AND KATABOLISM

Failure of Production of Prothrombin by the Liver.—(1) Degenerative or infective parenchymatous processes: Acute yellow atrophy; infective hepatitis. (2) Infiltrative parenchymatous processes. Generalized carcinomatosis; leukaemia.

Diminished Production of Prothrombin by the Liver.—Chronic hepatoses (Banti's syndrome, alcoholic cirrhosis); catarrhal jaundice; leukaemia; neoplasm of the liver.

Increased Destruction of Prothrombin.—Artificial fever therapy: prolonged fever.

In many conditions hypoprothrombinaemia results from a combination of pathological disturbances. This is especially true in intestinal diseases. Here, besides absorptive difficulties, there may be loss of vitamin K, and possibly of prothrombin, by excessive vomiting, diarrhoea, or the removal of succus entericus by a Wangensteen drainage tube. To this loss may be added the restricted dietary intake

* Preliminary investigations would suggest that when this latter finding is present it may be due to coexisting scurvy.

common in these patients and destruction of prothrombin by long-continued fever. Case 1, below, illustrates such a combination of circumstances.

When ulcerative conditions of the bowel are present and hypoprothrombinaemia develops, continuous haemorrhage from the lesion will occur when the prothrombin level has decreased to about 35% of normal. This is true of ulcerative colitis and regional ileitis, and possibly explains the intestinal haemorrhage seen in enteric fever. When the mucosa is intact, however, no melaena or haematemesis will become evident until the blood-prothrombin level has dropped to the spontaneous haemorrhagic level of from 15 to 20%. Such a condition is especially common in haemorrhagic disease of the newborn and is sometimes found associated with idiopathic steatorrhoea.

Dietary deficiency *per se* rarely causes a haemorrhagic hypoprothrombinaemia (Kark and Lozner, 1939). We have, however, observed an infant with rickets of dietary origin who developed a spontaneous subarachnoid haemorrhage; the blood-prothrombin level was extremely low, being 20% of normal. The prothrombin level was rapidly restored to normal by therapy with synthetic vitamin K parenterally, and the child made an uneventful recovery following craniotomy and evacuation of the blood clot.

In idiopathic steatorrhoea, although a hypoprothrombinaemia does occur as a result of failure of intestinal absorption while a mixed diet is being taken, a haemorrhagic level is not reached unless the patient is on a low-fat diet (Kark and others, 1940). As a result of such a regime fat-soluble vitamins are markedly restricted, and within six months to two years features of spontaneous haemorrhagic hypoprothrombinaemia may appear.

Metabolic Disturbances of Prothrombin Anabolism and Katabolism

The manner in which the production and destruction of prothrombin in the body take place is not clearly understood, and for this reason any classification on the basis of metabolic disturbances of prothrombin formation or breakdown must of necessity be tentative. It has long been known that prothrombin is sensitive to heat and is readily destroyed by a temperature of 40° C. in a water-bath. Prothrombin studies were therefore made on patients undergoing artificial fever therapy. The results obtained were inconclusive. However, Wilson (1939) reported observations on a series of patients undergoing artificial fever therapy who developed a severe haemorrhagic diathesis and pronounced hypoprothrombinaemia. As yet it is not clear whether high pyrexia during the course of a disease is in itself capable of hastening the destruction of prothrombin in the blood, but it would appear that in patients with hypoprothrombinaemia a sudden high fever may accelerate the rate of destruction of prothrombin.

In newborn infants a physiological drop in prothrombin occurs after birth and, reaching a low level four or five days later, gradually returns to normal (Brinkhous and others, 1937; Waddell and Guerrey, 1939). When this physiological drop becomes marked, haemorrhagic disease of the newborn develops. Castle (1939) has suggested that this condition is a nutritional disease dependent perhaps on a maternal deficiency or on the deficient synthesis of vitamin K in the newborn before the intestinal bacterial flora becomes established. While this may be true it would seem that other factors may also play a part in the production of haemorrhagic disease of the newborn through over-activity of normal physiological processes which occur after birth. Although Kugelmass and Tritsch (1929) reported low prothrombin concentrations in the blood of a mother whose infant developed haemorrhagic disease of the new-

born, the test they used was not specific for prothrombin. Since the introduction of more specific tests and the consequent revival of interest in blood prothrombin concentration in the newborn no reports have been published of a diminished prothrombin level in mothers of infants suffering with haemorrhagic disease of the newborn, nor have we been able to find any reduction of the prothrombin in the mothers of babies with prothrombin deficiency whom we have studied. It is known that in premature infants the physiological reduction in the prothrombin concentration level is greater, and haemorrhagic disease of the newborn is more common, than in infants born at full term (Shetles and others, 1939; Kato and Poncher, 1940). In a premature infant the general body metabolism is much increased, and it may then perhaps be true that a severe fall in blood prothrombin in a newborn infant is an index of an abnormally raised metabolism, with a consequent increase in the normal physiological process of blood-prothrombin reduction.

Hypoprothrombinaemia and the Prognosis of Patients with Liver Disease

Since Quick and others (1935) first reported the association of hypoprothrombinaemia with various types of jaundice numerous authors (Quick, 1938; Butt and others, 1939; Scanlon and others, 1939) have noted that patients with parenchymatous disease of the liver may have a low blood prothrombin which does not respond to therapy with vitamin K and bile salts. This failure of response is due to total or partial failure of the mechanism by which prothrombin is formed. Preliminary observations (Kark and Souter, 1940) on this phenomenon have shown that patients with liver disease and hypoprothrombinaemia may be divided into two main classes: those whose liver disease is so severe and widespread that they are *totally unable* to manufacture prothrombin; and those with more chronic and less widespread liver damage who are able to manufacture *some* prothrombin. In such patients it was not possible to correct the hypoprothrombinaemia by therapy with natural and/or synthetic vitamin K, supplemented in some cases by transfusion or therapy with large amounts of liver. The first group, with severe liver disease, always developed a haemorrhagic hypoprothrombinaemia; and all the patients in this group died within a short time of their admission to hospital. The second group, who also did not respond to therapy, never developed a haemorrhagic tendency (i.e., the blood-prothrombin concentration always remained above 35%), and were eventually discharged from hospital. Further studies have confirmed these observations, and it is now believed that if a patient with liver disease develops a severe hypoprothrombinaemia (below 35%) which is *resistant* to vigorous treatment with parenteral vitamin K in large doses, then the immediate prognosis is very grave. The immediate prognosis of the second group is good, but since they have been studied only during the nine months before writing this paper it has not been possible to assess their prognosis correctly on the basis of the prothrombin level of their blood. It is likely, however, that the Quick test, used in conjunction with vitamin K therapy, may become a useful liver-function test. The following case is illustrative:

A young boy suffering from acute rheumatic fever and severe congestive failure developed an acute parenchymatous hepatitis during his illness. He was extremely ill with cholaemia, and a severe haemorrhagic tendency became evident. On clinical and laboratory evidence he was given a bad immediate prognosis. His prothrombin level at the height of his illness was found to be 24% of normal. Following injection of synthetic vitamin K the prothrombin concentration rapidly and unexpectedly increased to well above the level for haemorrhage, but

remained between 45 and 50% of normal, despite further treatment. On this basis it was felt that his immediate prognosis, notwithstanding the other observations, was good. At present, six months after the acute episode, he has a chronic hepatitis with ascites, and his prothrombin level has not yet returned to normal.

In this patient it is probable that a moderate metabolic disturbance in the manufacture of prothrombin was accompanied by a failure of absorption of vitamin K from the gut because of obstructive jaundice due to hepatic cell swelling, with subsequent pressure on the intrahepatic ducts.

Hypoprothrombinaemia and the Diagnosis of Obstructive Jaundice.—When the patient with intense jaundice and acholic stools presents a problem in differential diagnosis the rapid return of a lowered prothrombin concentration to a normal figure following the administration of adequate doses of parenteral vitamin K is strongly suggestive of obstructive jaundice.

Haemorrhagic Conditions unassociated with Hypoprothrombinaemia.—In patients with haemophilia, purpura haemorrhagica, thrombocytopenia, "idiopathic" menorrhagia, polycythaemia, and other blood dyscrasias the blood-prothrombin levels were within normal limits. When vitamin K was given to some of these patients it was, as anticipated, without effect on their haemorrhagic diatheses. In patients who had bled from peptic ulcers the blood-prothrombin level was but little reduced even when haemorrhage had been severe. This reduction in blood-prothrombin concentration paralleled the amount of prothrombin lost with the blood from the lesion, and was never severe enough to perpetuate the haemorrhage by reason of prothrombin depletion.

Treatment of Hypoprothrombinaemia

The development of synthetic analogues of vitamin K has rendered the use of natural vitamin K, together with bile salts, unnecessary. The synthetic substances are more effective, their dosage is more easily standardized, and they are less expensive to manufacture. Of the numerous known synthetic compounds with vitamin K activity, 2-methyl-1:4-naphthoquinone, described in detail by Ansbacher and Fernholz (1939a), is most active, and it is at least three times as potent as natural vitamin K (Ansbacher and Fernholz, 1939b). This yellow crystalline substance is only slightly water-soluble and is not easily adaptable for parenteral use.

Recently Moore and Kirchmeyer (personal communication) have synthesized a water-soluble compound, 2-methyl-1:4-naphthohydroquinone-3-sodium-sulphonate,* which is made up so that 1 c.cm. of an isotonic solution containing it is equivalent in vitamin K activity to 2 mg. of 2-methyl-1:4-naphthoquinone. This material is potent and easily administered parenterally; no toxic symptoms have been noted referable to its use in the dosage given (Kark and Souter, 1940).

Since the experience in this laboratory has been limited to the use of these two compounds and natural vitamin K no mention will be made of any of the many other synthetic analogues of vitamin K.

Parenteral Therapy

In the treatment of haemorrhage resulting from hypoprothrombinaemia the parenteral compound is most useful, and intravenous administration of the drug is most effective in checking active bleeding: a haemorrhage is controlled within one and a half to three hours after injection, while the blood-prothrombin level rises rapidly and reaches a

normal level within twenty-four to forty-eight hours. A single intravenous injection, however, will not maintain a normal concentration, and the prothrombin level will fall within the succeeding twenty-four hours and may rapidly return to a level at which there is danger of haemorrhage.

A single intramuscular injection, while not so effective in the rapid control of haemorrhage, will, however, maintain a normal level of prothrombin in the blood for some days. It is therefore advisable, in a patient presenting active haemorrhage, to give both intravenous and intramuscular injections of the water-soluble compound in order that the maximum advantage of each route of administration may be utilized in raising the prothrombin concentration of the blood rapidly and in maintaining it at a high level.

When given parenterally, 1 to 3 c.cm. of the water-soluble compound (equivalent to 2 to 6 mg. of 2-methyl-1:4-naphthoquinone) has been found sufficient to control haemorrhagic hypoprothrombinaemia in the presence of a normal liver (see case records and Fig. 3).

In patients with hypoprothrombinaemia who are vomiting actively, or in those patients suffering from gross intestinal absorptive difficulties, one intramuscular injection of 3 c.cm. of the water-soluble compound will usually restore the prothrombin level to normal and maintain it at a high level for from four to six days.

Oral Therapy

The first clinical application of therapy with vitamin K was to treat patients suffering with disease of the biliary passage and hypoprothrombinaemia by the administration of natural or synthetic vitamin K orally in an oily vehicle together with bile salts or bile given by duodenal tube. Many of these patients developed nausea, vomiting, or diarrhoea as a result of taking the bile preparations. Preliminary investigations, however, on a few patients who had complete biliary obstruction (as evidenced by the absence of urobilinogen from their stools) and hypoprothrombinaemia have shown that 2-methyl-1:4-naphthoquinone when made up in tablet form is absorbed from the alimentary canal in the absence of bile salts. In these patients 2 mg. of the material given three times a day will control the hypoprothrombinaemia (see case records and Fig. 4). Smith and Owen (Moore and Kirchmeyer, personal communication) have successfully treated similar cases by administration of a water-soluble naphthol without bile salts.

In patients with nutritional deficiency or in patients with idiopathic steatorrhoea 1 mg. of 2-methyl-1:4-naphthoquinone given daily will usually suffice to control hypoprothrombinaemia or prevent its appearance (Kark and others, 1940).

Prophylaxis

There is good evidence to show that the prothrombin level of babies born of mothers treated with vitamin K before labour is higher than that found in babies of mothers who have not been so treated (Shettles and others, 1939). Ideally, it might be advisable to give pregnant women at least 2 mg. of 2-methyl-1:4-naphthoquinone daily during the last week of their pregnancy, and to feed or inject a similar dose to the baby soon after birth. If the latter therapeutic measure alone were to be adopted as a routine procedure haemorrhagic disease of the newborn would become an extremely rare condition.

It is probable that in the future vitamin K or one of its analogues will be given as a routine pre-operative measure to patients suspected of having hypoprothrombinaemia. It is proper to emphasize at this point that the administration of therapeutic doses of vitamin K or its analogues, before operation is not in itself a guarantee that the blood-

* Now known as hykinone, and produced by Abbott Laboratories, N. Chicago, Ill.

prothrombin concentration will be raised to within normal limits. Indeed, in certain patients with liver disease this effect is not accomplished. For this reason it is always necessary to determine the blood-prothrombin concentration immediately before operation, even when vitamin K or one of its analogues has been given in amounts considered adequate. When the prothrombin level is found to be low in spite of such treatment, transfusion of fresh blood or plasma is the only known therapeutic measure which can increase the prothrombin concentration of the blood. The indiscriminate administration of vitamin K to patients showing a bleeding tendency without establishing that the condition is one of haemorrhagic hypoprothrombinaemia is to be deplored. Therapeutic failure in such cases may unjustly throw discredit on a valuable and specific remedy.

Illustrative Cases

Case 1 (Fig. 2).—A poorly nourished young girl aged 18 suffering with regional ileitis developed an intraperitoneal abscess

FIG. 2.—Case 1. The effect of intramuscular natural vitamin K (6,000 Dann units) on the blood-prothrombin percentage and haemorrhagic tendency of a patient with regional ileitis.

FIG. 3.—Case 2. The effect of 3 c.cm. of water-soluble vitamin K on the blood-prothrombin percentage, coagulation time, and haemorrhagic tendency of a patient with stenosis of the common bile duct. (Each cubic centimetre of water-soluble vitamin K is equivalent to 3.2 mg. of 2-methyl-1:4-naphthohydroquinone-3-sodium-sulphonate.)

after a laparotomy. Her post-operative course was extremely stormy. She had hectic fever, diarrhoea, vomiting, and mild dementia. Haemorrhage occurred from the bowel and from the abdominal wound. The blood-prothrombin concentration was markedly reduced, but treatment with 4 c.cm. of intramuscular natural vitamin K (6,000 Dann units) controlled the haemorrhage and restored the blood-prothrombin level to normal.

Case 2 (Fig. 3).—A woman aged 42 suffering from traumatic stricture of the common bile duct had had recurrent attacks of obstructive jaundice for ten years. During this time she had on many occasions developed a haemorrhagic diathesis, which was uncontrolled by therapy. On her admission to hospital her blood-prothrombin concentration was less than 5% of normal and she was bleeding from her nose and gums. Intramuscular injection of 3 c.cm. of water-soluble synthetic vitamin K (equivalent to 6 mg. of 2-methyl-1:4-naphthoquinone) controlled the bleeding within one and a half hours, and the blood-prothrombin concentration returned to normal by the next day. Since this time the patient's blood-prothrombin concentration has been maintained at a high level by treatment with injections of the water-soluble compound or by the oral administration of 2-methyl-1:4-naphthoquinone.

Case 3 (Fig. 4).—A woman aged 73, with carcinoma of the pancreas, developed a painless obstructive jaundice which was complete. Marked bruising appeared at the site of a venepuncture and her blood-prothrombin concentration was found to be severely reduced. Oral administration of 2-methyl-1:4-naphthoquinone without the bile salts restored the prothrombin

FIG. 4.—Case 3. The effect of oral administration of 2-methyl-1:4-naphthoquinone without bile salts on the blood-prothrombin percentage of a patient with carcinoma of the pancreas and obstructive jaundice. (Each small black represents 2 mg. of 2-methyl-1:4-naphthoquinone.)

level to normal, and surgical intervention was successfully accomplished without abnormal haemorrhage. While she remained in hospital she was given 4 mg. 2-methyl-1:4-naphthoquinone each day to maintain her blood-prothrombin concentration at a high level.

RUPTURE OF THE DRUMHEAD AS A WARTIME INJURY

BY

ALFRED B. ALEXANDER, M.D., L.R.C.S.

Rupture of the drumhead is a common peacetime injury; and when the present emergency has become a matter for clinical-statistical investigation rather than for clinical action, and more complete statistical figures are available, it might well prove the most common of all types of injury due to aerial bombardment. The frequency of rupture of the tympanic membrane under air-raid conditions is no surprise. Reports from Barcelona had suggested it, and in a recent discussion Miss J. Collier (1940) quoted R. Trueta's Barcelona figures, indicating that from 30 to 60% of the Barcelona air-raid casualties had sustained damage to the drumhead.

Rupture of the tympanic membrane in peacetime is a slight injury. But it only remains a slight injury when it is followed by an uncomplicated course, free from infection of the tympanic cavity; and there is evidence to believe that this uncomplicated course, which is the rule in peacetime injuries, is less frequent when the injury is due to the blast of high-explosive bombs. Once infection establishes itself inside the tympanic cavity the whole chain of aural afflictions and otogenic complications, ranging from slight persistent deafness to death from meningitis, is a possible outcome of the injury.

Apart from those ruptures of the tympanic membrane which are caused by the extension of a fracture of the cranial bones to the membrane, it is customary to differentiate between direct and indirect traumatic ruptures. The direct ruptures are caused by a great variety of foreign bodies and by over-powerful syringing of the meatus for the removal of wax. The indirect ruptures are due to sudden changes in the density of the air in the meatus, aided by complete blockage of the air in the meatus at the moment of the influence of the force. The most common causes of such indirect ruptures are blows on the ear, particularly the slap with the open palm occluding the meatus, and inadequate head-first dives into the water. Most textbooks include the rupture of the membrane due to explosions among the indirect ruptures, but this is wrong. The rupture is a direct one caused by the extremely powerful concussion of the air by the explosive—the "wave of pressure" (Zuckerman, 1941). All these differentiations, however, are only of theoretical interest.

From the practical point of view it is best to distinguish between ruptures which leave the tympanic cavity most probably sterile (slap on the ear), and ruptures in which the sterility of the tympanic cavity has been interfered with (syringing, diving). These two clinical types of rupture are often followed by a different clinical course. Ruptures of the drumhead caused by blast must be regarded as belonging to the second group, as it is always likely that foreign matter, carried by the blast, has entered and possibly infected the tympanic cavity.

Symptoms

Indirect ruptures of the drumhead can remain symptom-free, particularly in cases of previously reduced hearing or diminished resistance of the membrane. In air-raid casualties the symptoms are often masked by the presence of more severe injuries and, lacking routine otoscopy, such cases are in danger of being overlooked until suppuration occurs.

In most cases, however, at the moment of the rupture a short stabbing pain is felt, frequently accompanied by

tinnitus or the hearing of a high-pitched sound. Initial vertigo is very common. Some pain persists for a few hours or even days. Hearing is moderately reduced. In many cases a trying feeling of fullness in the ear, occasional giddiness and sickness, headaches, and a certain amount of deafness persist for considerable periods. The vertigo, particularly that immediately following the injury, deserves a few words of explanation. It is not, as commonly suggested, caused by some "concussion of the labyrinth," but is simply explained as being the effect of cold caloric irritation, caused by cold air. The air normally contained in the tympanic cavity is warmed by its passage through the nose and Eustachian tube. Following the injury, cold air suddenly gains access to the middle ear and irritates the labyrinth. I have found in such cases that vertigo and nystagmus can be re-elicited, and the direction of the latter characteristically changed, by alternately placing a bottle filled with ice and a hot-water bottle in front of the external canal. The irritation of the labyrinth by cool air is one of the reasons for keeping the meatus closed following such an injury.

Signs

In fresh cases the most common finding on the drumhead is that of a roundish, irregular, or slit-shaped perforation, the latter usually in a radial position. The margin of the perforation is often frayed and irregular, and sometimes a flap, exposing an angular-shaped perforation, is folded towards the skin of the meatus. These "everted edges" of the perforation are not, as recently suggested, due to the "wave of suction" that follows the pressure-wave of the blast, but are quite common peacetime findings, and are described in old textbooks. A small zone around the margin of the perforation is discoloured and stained by the extravasation of blood. The remaining part of the drumhead is unchanged, but may show small interstitial haemorrhages; the latter findings are particularly common in blast injuries, in which also minute blackish spots sometimes occur, due to the impregnation into the membrane of small solid matter contained in the blast. A certain amount of blood, or coagula, in the meatus is a very common picture; and in air-raid casualties the whole of the meatus may be blackened by soot. In fresh cases the yellow colour of the normal mucous membrane of the medial tympanic wall is easily distinguished through the perforation, its yellow ("bone-yellow") colour forming a distinct contrast to the blood-stained margin of the perforation.

The perforation is more often situated in the anterior than in the posterior quadrants. Any anatomical detail of the contents of the middle-ear cavity, such as stapes, chorda tympani, or round window, can on occasion be seen through the perforation, should it happen to lie within the line of sight; and such structures will show a typical parallax phenomenon on movements of the observer's head. In cases in which there is no suspicion of a fracture to the base of the skull it might be permissible to remove carefully blood crusts, coagula, or wax by means of a sterile probe or aural forceps, should such structures render inspection of the drumhead impossible. The use of the syringe, however, is always and most strictly contraindicated.

It is usually easy, but quite unnecessary, to demonstrate the presence of the perforation by certain tests such as the Valsalva experiment, Kugel's test, or "reversed politizerization." The hearing is moderately reduced, the tuning-forks revealing a deafness of the conductive (middle-ear) type. It is advisable to test for a reduction in the perception of high sounds, and for nystagmus (other than that produced by cold caloric influence from the air), which in complicated cases reveal damage to the labyrinth.

The diagnosis presents no difficulties in a fresh case. The blood-tinged irregular margin of the perforation is quite characteristic. In cases of longer standing, however, the shape of the perforation might have already become round and regular, and the extravasated blood be resorbed. In such cases diagnosis from a pathological perforation might become exceedingly difficult unless the history helps to clear the case.

Clinical Course

Traumatic rupture of the drumhead will lead to one of the following three types of clinical course.

1. *Uncomplicated Cases.*—The perforation gradually diminishes in size, while normal drumhead tissue regenerates. Complete healing ensues, and after the regeneration of the drumhead is complete it is quite impossible to recognize any trace of the site of the previous perforation. Drumhead and hearing regain perfect normality. The average duration of the healing process of such cases is twenty-five days.

2. *Infection of the Tympanic Cavity of Low Virulence.*—Minor inflammatory reactions appear within one to three days after the trauma. There is sero-purulent discharge, lasting from a few days to several weeks. Such cases often heal with the formation of atrophic scars followed by chalk deposits in the membrane, with chronic adhesive changes (synechia) in the middle ear, or with a persistent perforation. According to these changes, the hearing capacity is permanently somewhat reduced (middle-ear deafness).

3. *Infection of the Tympanic Cavity of High Virulence.*—Major inflammatory reactions, constituting the suppurative otitis media of post-traumatic origin, appear usually not later than twelve to twenty-four hours after the injury.

There are few indications in the literature regarding the relative frequency of these different types. It is obvious that ruptures which leave the tympanic cavity sterile stand a far better chance of an uncomplicated course than those in which the sterility has been interfered with. Water is the most common source of infection in peacetime, and therefore rupture due to diving or syringing is often followed by inflammatory reactions. It is a complete fallacy to think that the routine use of sterilized water for syringing could prevent infection in cases of accidental rupture, since the meatus, with which the water has always been in contact, is never sterile. However, taking into consideration both the uninfected and the possibly infected type of rupture, a survey of a large number of cases at the Neumann Clinic several years ago left me with the impression that at least some 80% of all peacetime ruptures follow an uncomplicated course to normality of drumhead and hearing. This proportion seems to be quite different in blast injuries, as over 50% of the cases caused by air raids which I have seen showed some infection of the tympanic cavity. Admittedly I am judging from a small number of cases, but the experience of a few colleagues with whom I have discussed the matter points in the same direction. It is therefore of great importance that in all cases of rupture of the drumhead caused by blast the tympanic cavity should be regarded as presumably infected, and treated accordingly.

Treatment

The object of treatment is best expressed in T. B. Layton's words—"to get well every single case under one's care. And by 'well' I mean a dry ear, a normal drumhead, and perfect hearing." This is achieved simply enough when the tympanic cavity has remained free from infection. In such cases the treatment should be restricted to the protection of the tympanic cavity from external influences that may cause further damage. No unnecessary manipulations in the meatus should be undertaken. Syringing as well as all types of ear-drops, whether contain-

ing water, peroxide, spirit, glycerin, or any other fluid, are strictly contraindicated. It is sufficient to plug the meatus lightly with sterile ribbon gauze or cotton-wool, and to inspect once or twice a week. The patient must be advised to take great care while washing his face or taking a bath—or, in the case of a woman patient, while having her hair washed or "set"—lest water should enter the meatus. The taking of violent forms of exercise should be avoided, as sweat might accumulate in the meatus and infect the middle ear.

It is the other type of rupture, in which foreign matter has entered the tympanic cavity, that presents the problem, and, as stated above, all ruptures of the drumhead caused by blast belong to this group. Complete healing and perfect hearing are guaranteed only when the tympanic cavity remains free from inflammatory reaction. Even minor inflammatory reactions might lead to some degree of permanent deafness with all its implications, and poor results obtained during the present emergency might increase the rate of deafness among the post-war population to a very considerable degree owing to the frequency of this injury. Perfect results depend on the prevention of the trauma leading to infection. But how can a tympanic cavity contaminated by blast be protected against the occurrence of such infection?

Insufflation of Sulphanilamide.—Impressed by the frequency with which suppuration follows rupture caused by air raids, I have recently started to treat all such cases as early as possible with a preventive insufflation of powdered sulphanilamide into the tympanic cavity. My results have so far been highly satisfactory, and although fully realizing that the results of all preventive methods are particularly liable to misinterpretation, and that the experimental data at present available on the topical use of sulphonamides are not convincing, I feel satisfied that early insufflation of sulphanilamide powder into a possibly or presumably infected tympanic cavity will reduce to a minimum the number of cases of subsequent suppuration in the middle ear.

I have also tried the insufflation in cases already infected, but have failed to observe any benefit, the powder just being swept away by the discharge. And cases of acute otitis of traumatic origin should be treated by the oral administration of a sulphonamide in the same way as it is used in otitis not of traumatic origin.

Technique of Insufflation.—This is very simple so long as the ordinary forehead-mirror and not an electric auriscope is employed. The site of the perforation is focused, and a few puffs from a straight powder-insufflator, administered through the speculum under guidance of the otoscopying eye, are quite sufficient. It is necessary to look into the ear in order to make sure that the powder not only coats the walls of the meatus but actually reaches the tympanic cavity through the perforation. Afterwards the meatus is lightly plugged and the patient advised as to the protection of his external canal.

The insufflation of powder into the middle ear is so simple, the results are so promising, and the aim of preventing infection is so important that I have no hesitation in recommending it as a routine treatment for rupture of the drumhead in the present emergency. It can cause no harm whatsoever, and if tried on a large scale and found successful it will also serve as a further argument in the demand for the routine otoscopy of all air-raid casualties.

RECOVERY FROM URAEMIA FOLLOWING CRUSH INJURY

BY

RONALD G. HENDERSON, B.Sc., M.B., Ch.B.,
F.R.C.S.Ed.

Resident Surgical Officer at an E.M.S. Hospital

As pointed out by Surgeon Lieut.-Commander Maitland (1941), isotonic sodium sulphate solution has been advocated as a potent diuretic from time to time. In view of the original oliguria and raised blood pressure in the case reported below it was considered unwise to give more than a pint at a time; it seems now that a larger initial dose, given slowly, might have produced more rapid results.

I have no original suggestions to make on the pathogenesis of the condition, but it is obvious from a consideration of this case and of the one reported by Mayon-White and Solandt (1941) that the syndrome is not produced by transfusion of incompatible blood and that it is not a nephritis of an ordinary type. It seems that the syndrome is the result of prolonged compression of a limb, or limbs, with subsequent release of pent-up katabolites of a toxic nature having a characteristic action on renal epithelium. While the renal lesion may be progressive up to a point, the first (fatal) case reported by Bywaters and Beall (1941), in which the affected limb was amputated on the second day, suggests that renal damage may be gross at an early stage; while the present case, together with R. V. Christie's case (quoted by Bywaters and Beall), proves that the lesion is not necessarily a fatal one. Furthermore, on superficial examination it seems that many air-raid casualties, and presumably civil accident cases, that have not been subjected to prolonged or severe crushing exhibit granular casts in their urine and have mild degrees of oliguria for variable periods. Research on these points seems to be indicated.

Case Record

A man aged 32 was admitted to hospital as an air-raid casualty on May 7, 1941. From about 1 to 9 a.m. on May 6 he had been pinned down by heavy debris across his left shoulder and

Chart of Case. Continuous line=output of urine in oz. per day. Thick broken line=output of urine in gm. per day. Fine dotted line=blood urea in mg. per 100 c.cm.

upper arm; he had suffered no other serious injury. He had received first-aid treatment in the neighbourhood of the air raid and had been in bed in a damaged hospital for about thirty-two hours before being transferred. No transfusions had been given.

On admission his general condition was very satisfactory. The left arm was grossly swollen and reddened, and numerous wheals

were present on it. Movement at all the joints of the limb was very restricted, and there was anaesthesia from the mid-arm distally. The circulation was intact and the radial pulse palpable. The possibility of renal failure developing was considered at this point, but no prophylactic measures were taken other than to administer fluids by mouth. The arm was wrapped in cotton-wool and elevated.

On May 10 he suffered from hiccup for a short while. This became more persistent in the next forty-eight hours. The tongue was dry, for the first time, on the morning of the 12th. and despite a liberal intake of fluid the output of urine for the preceding twenty-four hours had been only 30 oz. The blood urea was 390 mg. per 100 c.cm. Active treatment was begun immediately, 40 c.cm. of 25% glucose being given intravenously, followed by 540 c.cm. of isotonic sodium sulphate solution. During the next few days the output of urine and, later, of urea was measured; the blood urea was estimated daily while intravenous sodium sulphate solution in 540-c.cm. doses was given. The clinical course is shown on the chart.

During May 12-16 the tongue remained dry and coated and the patient was restless and rather childish, though otherwise rational. On the 17th his local and general condition began to improve and thereafter continued to do so. At the beginning of June there was still some loss of power in the whole limb, but no swelling and no anaesthesia; and some hyaline and a few granular casts were present in the urine. (At the beginning of the illness there were very numerous granular casts, no hyaline casts, a few red blood cells, but no blood casts and no reaction to the guaiac test.)

The patient had never suffered from nephritis or any disease likely to predispose to it.

Summary

A case of limb-crush injury with subsequent uraemic manifestations and recovery is briefly described. A short discussion on the production of the lesion in the light of previously recorded cases is given. It is suggested that mild cases may have previously passed unnoticed and that they may result from injuries of different types.

I am grateful to Dr. W. J. Richard and Mr. A. M. Clark for permission to publish this case. I wish also to thank Dr. T. C. Ritchie for much helpful advice, and Mr. A. W. Mollison for the preparation of the various solutions used and the numerous blood and urine analyses.

MEDICAL RESEARCH COUNCIL OF IRELAND

The Medical Research Council of Ireland has made the following awards during the half-year ended June 30, 1941. Training grants: Miss D. A. Kilbride for one year from August 1, 1941, to carry out an investigation of iodine absorption by means of Balance experiments; and Miss E. O'Donovan for one year from June 1, 1941, to assist in the investigation of the goitre problem by studying the retention of iodine under varying conditions of diet, the work in both instances to be done in the department of chemistry, University College, Cork, under the direction of Prof. J. Reilly and Dr. E. M. Mason. Whole-time grant: Dr. Cecil Mushart for four months from March 1, 1941, to enable him to continue his research work at the Johns Hopkins Hospital, Baltimore, Maryland, U.S.A. Grants-in-aid: Dr. James Deeny for six months from July 1, 1941, to investigate the relationship of vitamin C to the formation of complement and the relationship of both to immunity; Dr. D. K. Malley to investigate the effects of the cortical hormone on a case of pre-adolescent type of adrenocortical syndrome; and Dr. J. G. Waugh towards the expenses of his research work on sulphonamide therapy in the School of Physic, Trinity College, Dublin.

The following grants have been renewed for one year: Dr. T. E. T. Bradshaw (from March 1, 1941) and Prof. Hans Sachs (from May 1, 1941). Prof. J. B. Gatenby and Dr. R. G. Cross have relinquished their grants.

ALLERGIC SHOCK FOLLOWING A
SCHULTZ-CHARLTON TEST

BY

R. M. CALDER, M.B., Ch.B.

Surgeon Lieutenant, R.N.V.R.

The following case was considered worth reporting in view of the severity of the reaction induced by a Schultz-Charlton test. A brief survey of the literature has not revealed a similar case.

Clinical History

The patient, a youth aged 18, was admitted to hospital on October 2, 1940, as a possible case of scarlet fever. His illness had begun during the previous night with generalized itching of the skin and mild nasal catarrh. On rising he had discovered a rash on his body and limbs. Slight sore throat was also complained of, but he did not feel really ill. There had been some epistaxis that morning. On examination he was found to be thin but healthy-looking; he was afebrile and his pulse was 80. Over the trunk and upper parts of the limbs, but most intense over the front of the chest, there was a rash consisting of a diffuse erythema with a suggestion of urticaria in places. The face and neck were unaffected. His tongue was clean and his throat appeared normal.

The diagnosis at this stage seemed to be urticaria rather than scarlet fever; and on inquiry the patient stated that he had eaten tinned salmon for supper the previous evening and that six weeks previously he had had a similar rash, which had cleared up in a few days. The appearance of the rash on the front of the chest did, however, suggest scarlet fever, and to exclude this a Schultz-Charlton test was done, 0.2 c.cm. of anti-scarlatinal serum being injected intradermally over the lower ribs on the left side at a point where the rash was most intense. Fifteen minutes later the patient was seized with sudden severe headache and vomiting, accompanied by a feeling of hotness and intense itching of the skin. Oedema of the face developed rapidly, so that soon his eyes were completely closed by swelling of the eyelids; simultaneously general massive urticaria appeared all over the trunk and limbs, affecting an area larger than and including the original rash. The skin was cold and clammy, the pulse rapid and thready, and the blood pressure 80/45. 5 minims of 1 in 1,000 adrenaline was injected slowly intravenously, and his blood pressure rose to 95/55, while the facial oedema diminished slightly. The urticaria subsided more slowly, and he felt weak and sleepy for some hours after the attack.

Inquiry was now made about his family and previous history. His mother, two brothers, and one sister all suffered from hay-fever. The patient himself had lived in America till the age of 12, and while there had had hay-fever every summer; after coming to this country he had no further attacks. When a child he had also suffered from sensitivity to poison ivy; he stated that contact with the plant was not necessary—urticaria resulted even at a distance of one foot. He had received inoculations for this when 13, with apparent benefit. At the age of 12 he had been inoculated against diphtheria in New York. So far as he knew these were the only occasions on which he had received injections.

October 3.—The giant urticaria had disappeared, leaving the rash much as it was on admission, although he still had some swelling of the eyelids. The site of the Schultz-Charlton test was surrounded by an intense ring of erythema, superimposed on the original rash. Generally he felt well and was afebrile, but his appetite was poor.

October 4.—The original rash was now fading and the facial oedema had disappeared. Scratch tests were performed on the left forearm as follows: pollen control, 0; pollen toxin, + after twenty-four hours. Saline control, 0; salmon protein,* slightly + in twenty-four hours, + in forty-eight hours.

October 6.—The rash had completely faded and he felt very well. Serum sensitivity tests were performed by intradermal injection on the right forearm: human serum (1:10) 0.2 c.cm., 0;

* An extract prepared from the brand of salmon consumed by the patient.

horse serum (1:10) 0.2 c.cm. ++++ in five seconds. The instant local reaction to horse serum was striking; within thirty seconds there was a ring of erythema about 5 cm. in diameter and a lymphangitis in the upper arm which could actually be seen moving up towards the axilla as a thin red line, advancing about 1 cm. per second. After ten minutes the local reaction was more marked and a broad band of lymphangitis extended right up to the axilla, where the glands were tender and slightly enlarged. Blood pressure 110. The patient's face was rather flushed, but his only symptom was a mild headache. After twenty minutes the face was very flushed, and quite rapidly oedema was seen to appear round the eyes and then over the face generally, exactly as it did on the previous occasion. He complained of a pricking pain behind the eyes and his nose felt blocked. The submaxillary salivary glands were noted to be enlarged and tender. On this occasion no vomiting occurred, but he had nausea and profuse sweating. There was also a brisk epistaxis. At this point the reaction was considered unduly severe, so a tourniquet was applied above the site of injection and adrenaline was injected subcutaneously into the other arm.

October 7.—There was still severe oedema round the eyes, and the site of injection was red and swollen. He complained of some pain at this point and also across the chest, but he had slept well and felt fairly fit. Later in the day he collapsed suddenly and was unconscious for a few minutes, and his skin was cold and clammy. Recovery was rapid.

Further Progress.—During the next few days the swelling of the arm gradually subsided and was followed by the appearance of bruising at the site of injection. He had no further general symptoms, and was discharged from hospital quite fit nineteen days after admission. A notation was made on his medical history sheet of his extreme sensitivity to horse serum, in view of the probable danger of a therapeutic dose of serum.

Discussion

This patient provided an interesting example of the "allergic diathesis." He had a family history of hay-fever and was himself sensitive to the following substances: (1) Poison ivy. (2) Pollen—confirmed by skin test. (3) Salmon protein. This was probably the cause of his original rash. The onset, with itchiness of the skin, a few hours after eating a brand of salmon to which he gave a positive skin test is very suggestive. (4) Horse serum. The dramatic result which followed the intradermal injection of 0.2 c.cm. of anti-scarlatinal serum was proved to be a true sensitivity to horse serum by the exactly similar response to normal horse serum—of which 0.2 c.cm. of a 1 in 10 dilution or 0.02 c.cm. of pure horse serum induced a severe reaction. Such a high degree of sensitivity is uncommon; indeed, a similar dose of serum has been recommended as a test of sensitivity before the intravenous injection of much larger quantities.

In the human being delayed reactions to serum (e.g., serum sickness) are much commoner than immediate reactions, to which the term "allergic shock" has been applied. This term is perhaps preferable to "acute anaphylaxis," since the latter implies that the sensitivity has been induced by a previous dose of serum (Lamson, 1929). In the present case it is possible that the diphtheria prophylactic at the age of 12 was the sensitizing dose. Various estimates of the frequency of serum sensitivity after diphtheria prophylactics have been made (Hooker, 1924; Gordon and Creswell, 1929). Tuft (1932) noted that sensitivity was more common in people with a family history of allergic disease, which was certainly positive in the present case.

Cases of allergic shock after the subcutaneous or intravenous administration of serum have often been reported; but only two references have been found to general reactions to serum given intradermally. Freedman (1935) recorded the case of a boy of 6 who died after the intradermal injection of 0.05 c.cm. of horse serum given nine

days after a dose of diphtheria toxin-antitoxin. Vaughan and Pipes (1936) described a case very similar to the present one in which a severe reaction was caused by 0.1 c.cm. of anti-tetanic serum given intradermally.

An interesting feature of our case was the rapidly spreading inflammation of lymphatic vessels and glands draining the site of injection. It is obvious that such a reaction must be due to the presence of some substance flowing along the lymphatic which causes dilatation of the surrounding capillaries as it travels. Whether this substance is the actual serum injected or some tissue product is unknown, but it is interesting to realize that 0.02 c.cm. of serum intradermally can produce such an intense and prolonged lymphangitis as was observed.

Summary

A case of allergic shock after the intradermal injection of horse serum is described in a youth aged 18, who was also sensitive to poison ivy, pollen, and salmon protein.

A severe systemic reaction was induced by as little as 0.02 c.cm. of serum given intradermally.

The case emphasizes the importance of skin-testing before the therapeutic use of serum, particularly in patients with a family or personal history of allergic disease.

I have to thank Surgeon Vice-Admiral S. F. Dudley for permission to publish this case.

Medical Memoranda

Treatment of Bacillary Dysentery (Flexner) with Sulphapyridine

In view of the increased incidence of bacillary dysentery (Flexner and Sonne) in this country during the past few months, the following note appears to be worthy of record. The results achieved are so striking that it is hoped that others who are faced with a similar epidemic may be induced to give this form of treatment a trial.

It was decided to employ sulphapyridine when bacillary dysentery showed itself at this hospital, owing to the results obtained by Drs. Reitter and Marberg published in the *British Medical Journal* of February 22 last. The opportunity occurred on April 26, when an epidemic of Flexner dysentery began. Sixteen male patients were treated, their ages varying from 22 to 67 years. They included patients suffering from various forms of chronic psychosis, and their general state of health was by no means uniformly good. - Three of them had suffered from bacillary dysentery on a previous occasion.

In this hospital, unfortunately, dysentery epidemics have occurred in the past, usually in the spring and autumn, and in consequence the experience of both the medical and nursing staff in the treatment of this unpleasant illness, at least so far as it affects mental patients, is considerable. Treatment previously has been determined by symptoms and according to the current belief of the medical officer concerned. It is all the more striking therefore when experienced nurses declare spontaneously that the course of the disease has been shortened with sulphapyridine by at least seven days.

Clinically the cases were of moderate severity, with temperatures as high as 104° F. and loose stools with the usual blood and mucus. Bacteriological examination in each case uncovered Flexner XYZ. With sulphapyridine the temperature fell to normal in most cases in twenty-four hours, and in all within forty-eight. The character of the stools improved more gradually, showing diminished blood and mucus and being formed

about the fifth day. In every case but one the stools were reduced to a maximum of two a day from the third day. The tongue, from being furred and dry at the outset, was clean and moist by the third or fourth day. The general condition improved in the same striking manner, the toxic appearance, characteristic of dysentery, rapidly disappearing. The drug was administered by the mouth as early as possible; that is, immediately upon the case being clinically diagnosed. A routine dose was adopted, namely:

1.0 gramme (two tablets)	4-hourly for the 1st day
0.5 " (one tablet)	4 " " 2nd "
0.5 " " "	6 " " 3rd "
0.5 " " "	thrice during the 4th "
0.5 " " "	twice " 5th "

Bicarbonate of soda was added wherever there was any tendency to nausea.

Diet	1st and 2nd days	Milk and water only
	3rd and 4th days	add arrowroot
	4th and 5th days	" " and mashed potatoes
	5th or 6th day	" " and pounded fish.

Bacteriologically all patients were Flexner-free (as determined by rectal swabs and plating) by the fifth day. Four consecutive negative swabs were considered to establish freedom from Flexner, and these were obtained in all the cases.

A most striking feature is the excellent general condition of the patients when they are allowed up, usually about seven days from the onset. In previous epidemics the patients have lost much weight and required several weeks of convalescence before they could be regarded as approaching normal health.

I am much indebted to Dr. Morris Robb for his careful treatment in this series of cases.

Brentwood, Essex.

W. GORDON MASEFIELD,
Medical Superintendent, Brentwood
Mental Hospital.

Amidopyrine and Pernicious Anaemia

We are accustomed to associate amidopyrine with the development of agranulocytosis, but Rhoads and Miller (1937) have shown that amidopyrine will depress the production of red cells in animals on a defective diet. Their work suggests that we should be very careful about the prescription of amidopyrine, and of drugs such as the sulphonamides and the organic arsenicals, to patients with pernicious anaemia, but the following is the first case in which I have seen amidopyrine depress erythropoiesis in man.

CASE RECORD

A married woman doctor came under treatment in 1934. She was 32 years old and had suffered from symptoms of pernicious anaemia for two years. The diagnosis was confirmed by the presence of achlorhydria, increase in serum bilirubin, and a characteristic Price-Jones curve. She was in a nursing home for three months, responded well to liver injections, and became fit enough to have a baby. A week after the baby was born she began to get corneal ulcers, and eventually in 1940 she stopped the injections of liver because it seemed possible that the corneal ulcers were a symptom of sensitization to liver. In January, 1941, she lost heavily at her period and in February she resumed the liver injections. On March 20, after weekly injections, her haemoglobin was 70%, but on March 26 it had fallen to 58%. Injections of liver were given on alternate days till April 1, and then daily, but although there was a moderate reticulocytosis the haemoglobin fell to 46% on March 31 and to a minimum of 44% on April 4. The white cells were normal. Naturally some serious complication was feared, but no evidence of any could be found. Inquiry then revealed that she was taking the hypnotic drug alional, which contains amidopyrine. On omitting this, and without making any other change in the treatment, she showed a reticulocytosis of 31% and a rapid improvement. By the end of June her haemoglobin had risen to 92% and the colour index and red cell volume had returned to normal. The tendency to corneal ulceration has unfortunately persisted.

Reviews

ALCOHOL AND SOCIETY

Confirming the Facts: A Manual of Scientific Temperance Teaching for the Use of Teachers and Students. With a foreword by Sir George Newman. (Pp. 128. 1s. 6d.) Bedford: Rush and Warwick (Bedford), Ltd.

Confirming the Facts is a small book described on the title-page as "A comprehensive and authoritative statement concerning alcohol, its nature and effects." It has been prepared by the Temperance Collegiate Association, and is intended as a manual of scientific temperance for the use of teachers and students. Here are articles by twelve authors, each of whom is a well-known authority on the aspect of the problem with which he or she deals. For example, Sir Gowland Hopkins has written on the relation of alcoholic beverages to nutrition, the late Lord Stamp on the economic aspects of temperance, and Sir Leonard Rogers on alcohol in the Tropics. As these names indicate, the general standard of the volume is remarkably high, and the variety of the contributors results in reliable information being provided on special features of the subject.

Mr. Liverseege, former public analyst to the City of Birmingham, gives a very clear account of the composition of alcoholic drinks, and in particular explains the mysteries of calculations in terms of proof spirit. The difficulty of such estimations is indicated by the fact that the author notes a serious error in tables given in the Medical Research Council Handbook, *Alcohol: its Action on the Human Organism*. This error was due to the use of American calculations, and unfortunately the U.S.A. proof spirit differs from the British proof spirit in respect of alcohol content. Special attention is paid to the economic aspects of expenditure on alcohol. This is very wise because, while drunkenness is diminishing, the under-nutrition caused by disproportionate outlay on alcohol is a problem that has become of increasing importance. Lord Stamp concluded that the working classes spent 15% of their income on alcoholic drinks, and that this consumption reduced industrial efficiency between 5 and 10%. It is usually assumed that most of the expenditure on alcohol returns to the Exchequer, but at the 1934 level of taxation the tax constituted only two-fifths of the sale price of beer. The barley and hops accounted for about 8% of the cost, while the labour cost was estimated to be about one-eighth of that created by the same expenditure in industry in general. The margin represented by cost of sale and profits is therefore substantial and explains the ability of the trade to sustain intense propaganda. Several of the contributors criticize the standards of accuracy of beer advertisements. Mr. Heath, who is secretary of the United Kingdom Alliance, makes some interesting points regarding the political activities of "the trade." The lack of enthusiasm of the Labour Party for temperance reform has been somewhat striking, and he notes that the working men's clubs have become a tremendous bulwark to protect the liquor trade. He points out the remarkable contrast between the care with which licensed premises are regulated and the lack of control of clubs.

It will be gathered that a wide variety of aspects of the alcohol problem is dealt with in this collection of papers. The more purely medical aspects are discussed by Sir Leonard Rogers, Sir William Willcox, Dr. Cove Smith, Mr. McAdam Eccles, and Prof. Amy Fleming. The Bishop of Worcester contributes an article on the Christian Ethics of Temperance. In price and size the volume resembles the

Medical Research Council book on alcohol, but the scope of the two is different. The M.R.C. book deals with the action of alcohol on the human organism, whereas the book under review is more concerned with the influence of alcohol on society. Most of the propaganda for and against "the universal solvent" is so biased and inaccurate as to be distasteful to the medical profession; hence this work is of special interest because it provides a short but objective survey of different facets of an important social problem.

PSYCHOTHERAPY

Psychotherapy. By Lewellys F. Barker, M.D. (Pp. 218. 8s. 6d. net.) New York and London: D. Appleton-Century Company. 1940.

Amidst the welter of psychological and psychiatric literature which pours from the presses on both sides of the Atlantic it is refreshing to find a small book written by an experienced physician who knows how to marshal his facts and enunciate his theories with a minimum of verbiage. Dr. Barker represents the psychobiological school of Adolf Meyer, which by its breadth of outlook and catholicity of therapeutic method is wielding much influence in psychiatry and is likely to wield more and more.

There can be no set rules for the treatment of disease, and if it is of paramount importance that we should not confine ourselves to the treatment of the body only, it is equally important that we should not limit our vision to one sort of psychotherapy or to one type of mind.

The psychiatrist requires a broad basis of knowledge of all types of mental reaction and of all methods of dealing with them, but the successful practitioner will be he who knows intuitively or by experience how to choose the method which will best suit not only the patient but his own reactions in dealing with the patient. All this Dr. Barker sets out in the present essay, and if he is not impressed by the claims of the psychoanalysts, he admits that in some few cases their methods may be serviceable at least in some psychoneuroses. For the psychoses he prefers general management and occupational therapy, but points out the value to psychotherapy in many cases of irreversible "organic" disease. At the end he calls attention to the effect of various poisons in reproducing certain psychotic reactions, and suggests that the future may provide other channels to reverse these processes, but he will admit that we do not yet know whether such poisons really cause these reactions or only unmask a psychic pattern already there, nor what that pattern owes to heredity, constitution, or environment.

If this book discloses how far we are from a full psychiatric knowledge which neither this generation nor the next may achieve, it shows how steadily we are marching towards the goal, and it should be read by all who have any claim to be considered up-to-date physicians.

MIXED MEDICAL FARE

The Practitioner's Library of Medicine and Surgery. 1940 Supplement. Supervising Editor, George Blumer, M.A., M.D. (Pp. 772; illustrated. 42s. net.) New York and London: D. Appleton-Century Company.

In reviewing this book it would be unfair not to make it plain that it is a Supplement designed to bring up to date a *Practitioner's Library* which is already in existence. It must be confessed, however, that it is a large and expensive volume which provides a curiously assorted fare. Much of it will appeal to the ordinary intelligent practitioner. There is a good and detailed description of the place of the sulphonamide drugs in therapeutics. Here it is noteworthy

that the indiscriminate use of sulphanilamide in pharyngitis and tonsillitis is condemned, and it is recommended that sulphanilamide be used in pharyngitis and tonsillitis only if the infection is severe and is one that is known to respond to chemotherapy. There is also a straightforward account of recent advances in knowledge of vitamin K and the vitamin B complex. The section on infectious diseases, on the other hand, is extremely recondite. Few general readers will be particularly interested in such subjects as epulis granulomatosa, or bejel—the syphilis of Bedouin children—or toxoplasmic encephalomyelitis, and few specialists would look for information on these subjects in a volume of this kind. Among blood diseases we note very elementary articles on leukaemoid reactions and haemophilia and a fully documented article on the rare condition Letterer-Siwe's disease. The cardiologistical articles on the venous blood pressure and the circulation time, on the relation between thoracic deformities and cardiac disease, and on cardiac confusion are appropriate and well written, but that on granulomatous myocarditis cannot be said to be practical, topical, or informative.

Our criticisms, therefore, are directed not so much against the range of subject matter, which might be expected to be diverse owing to the unpredictable directions which the growth of knowledge takes, as against its variable depth and quality. If we are to believe the advertisements, American practitioners have a voracious appetite for medical textbooks, and the most highly specialized books are sometimes described as essential additions to their bookshelves. Nevertheless, a book addressed to practitioners should not attempt too much, and the editors must keep a tight rein on their contributors to ensure that the whole team pulls in the same direction.

HOSPITALS UNDER FIRE

Hospitals Under Fire. But the Lamp Still Burns. Edited by George C. Curnock. (Pp. 148. 7s. 6d. net.) London: George Allen and Unwin Ltd. 1941.

In this volume—a very human document of very inhuman events—the editor has collected accounts by victims and eye-witnesses of the bombing of a number of British hospitals. If the descriptions in their manner are colloquial or journalistic they also bear the stamp of authenticity. The tales have not been adorned, because they need no adornment. They are tales of nights of terror and of simple courage on the part of men and women subjected to tests of a kind for which their ordinary lives had provided no training but for which an urgent necessity, created by the worst in man, discovered in his best an adequate response. Although the descriptions are concerned mostly with the experiences of the London hospitals (the Westminster, St. Thomas's, the London, Guy's, Great Ormond Street, and the Royal Chest Hospital all receive mention), the editor is particular to explain that it was not his purpose to select, and that at the time the book was compiled many more hospitals in London and the other great cities had been or were being similarly attacked. Neither space, time, nor the censor allowed inclusion of them all. In some cases, where a decoration has led to the disclosure of a name, the accounts of personal heroism are accompanied by a personal interview and a photograph. Other actors in the drama remain anonymous. All seem to have accepted inclusion only because it might help the hospitals and the cause. Many of the facts revealed are intensely moving, and if any further evidence against totalitarian war were needed it will be found in plenty both in the letter-press and in the very fine photographic illustrations which accompany each chapter.

Notes on Books

RITCHIE CALDER'S *Carry on, London!* (English Universities Press, 5s. net) is a tribute to the ordinary people, not only in London but in all the bombed cities, who worked on through the horrors of last autumn and winter with courage that nobody would have dared to foretell. It is also to some extent a condemnation of the official mind—not so much in its direct criticisms, which are few and moderate, but in the accumulated details that show the inevitable fault of officialdom—insufficient sympathy and kindness. It might be well for the medical profession, when it is considering reorganization, to bear in mind this lesson of how easily the human touch gets lost in regulations and in the intricacies of mass planning. In this war it is essential to keep the individual in mind, because it is so often the individual, and not a trained, disciplined soldier, who is fighting. When the war is over people will want the consideration they deserve, and Ritchie Calder's book will have served a purpose if it reminds us of this fact. At present the half-trained defence workers—the auxiliary firemen and roof spotters, the shelter marshals and wardens, first-aid parties, welfare workers—and the trained doctors and nurses too, have simply ignored red tape and done what was necessary with magnificent courage and initiative. It may be more difficult for them when the war is over, and the planners will need to be more careful not to lose sight of the people for whom they are planning. The book should be read for this reason, and also because few people will have had Ritchie Calder's opportunity for seeing so much of the picture as a whole.

The Board of Registration of Medical Auxiliaries has issued a third edition, dated May, 1941, of the *Chiroprodists' section of the National Register of Medical Auxiliary Services*. It is published from B.M.A. House, Tavistock Square, W.C.1. We have also received a second edition of the much smaller *Orthoptists' section of the Register*. It will be remembered that "orthoptics" (the practice and principles of the development of binocular vision in the case of squint) was recognized by the Board on the recommendation of the Council of the British Medical Association.

A ninth edition of *Macleod's Physiology in Modern Medicine* has been published by Henry Kimpton (50s. net). The eighth edition, of which a notice appeared in our issue of April 8, 1938, was largely rewritten by a group of authors each of whom contributed a section devoted to one of the major fields of physiology. That arrangement has been continued, and the general plan and purposes of the book remain unaltered. The same contributors have co-operated in bringing out this ninth edition; they have been joined by Howard J. Curtis, who has rewritten the chapters on electrical excitation and conduction of the nerve impulse; and Walter S. Root has contributed a chapter on the urinary bladder. Although several new chapters have been added others have been combined, and the total number has not been increased.

Preparations and Appliances

ROTENONE LOTION FOR SCABIES

Rotenone lotion (British Drug Houses, Ltd.) is described as a non-oily mucilaginous preparation containing 2% of rotenone. This is the active principle of derris; it is a powerful insecticide which was used extensively in agriculture and has in recent years been tried for scabies. The vendors supply a pamphlet which gives details of the method of application of the emulsion.

The advantages claimed for rotenone are that it is not expensive, is cleaner than sulphur ointment, and is quicker to apply than benzyl benzoate. The effective treatment of scabies is a problem that unfortunately is rapidly increasing in urgency. The methods in general use are not completely satisfactory, and hence rotenone deserves a careful trial.

THE HUMAN SEX-CHROMOSOMES

Owing to the striking peculiarities of sex-linked inheritance this mode of transmission of hereditary traits has long been known empirically in man. Thus Nasse's law described the transmission of such diseases as haemophilia, though many years had to pass before the underlying histological basis was discovered. Later still the proved existence of an X-Y human sex-chromosome pair, together with genetic and histological work on other forms, raised the possibility that the classical type of sex-linked inheritance might not be the only one. Y-borne abnormal genes, rare it is true, have been recognized in man. More recently J. B. S. Haldane,¹ deducing from observations on mammalian chromosomes the possibility of partial sex-linkage, gave a brilliant demonstration of its existence in the human subject. All types of sex-linked inheritance depend upon the simple behaviour of the sex-chromosome pair. It will be recalled that the human male and female differ in respect of this one pair out of the twenty-four. Whereas in the nucleus of the female somatic cell the two members of the pair are equal, being termed X-chromosomes, within the male nucleus is found one X-chromosome only, together with an unequal partner, termed the Y, a third the size of the X. After the reduction division, gametes are formed containing one member only of each chromosome pair. Thus all ova contain one X-chromosome, while half the spermatozoa contain an X-chromosome and half contain a Y. Should an ovum happen to be fertilized by an X-bearing sperm the result is an XX individual—that is, a female; should it happen to be fertilized by a Y-bearing sperm the result is an XY individual—that is, a male. This is the simple basis of the determination of the sex of the new individual.

Like the other chromosomes the sex-chromosomes carry genes affecting various bodily structures and functions. In classical sex-linkage—for example, in the case of haemophilia—the gene responsible for the abnormality is exclusive to the X-chromosome. Should it be recessive, another feature of the classical case, a female bearing the abnormal gene upon one X-chromosome is outwardly normal. Half her ova will, however, contain an X-chromosome bearing the abnormal gene. Should such an ovum be fertilized by an X-bearing sperm the result will be another outwardly normal carrier female. But should that ovum be fertilized by a Y-bearing sperm the result will be an affected son, for the Y-chromosome has no corresponding normal gene to oppose the action of the single gene borne upon the X. It is equally easy to see that a haemophilic man married to a normal woman will have children who are all outwardly normal, though all

daughters will in fact be carriers. This follows because to the normal X-chromosome contributed by the mother is added either a normal Y-chromosome, giving a normal son, or an X-chromosome bearing the gene for haemophilia, thus giving a carrier daughter. The female haemophilic could appear only if a haemophilic man happened to marry a carrier woman, and this is an extremely unlikely contingency. Thus haemophiliacs are males who have received the gene from their mothers; should they marry they transmit it in turn to their daughters, who are outwardly normal though in fact carriers.

Does the Y-chromosome carry abnormal genes? Instances have been found in other animals of genes exclusive to that chromosome and not found upon the X-chromosome. Hereditary transmission of a trait determined by such a gene is of a very simple description. The trait is exclusive to males and is never exhibited or transmitted by females. It is transmitted by an affected man to all his sons. A few rare examples of this kind of sex-linked inheritance have been discovered in the human subject. Easily the most remarkable is the "porcupine" family described by Cockayne.² This truly astonishing mutation has apparently been recorded once only in the history of the human race. In ordinary chromosome pairs an interchange of segments takes place before the reduction division. This has the effect of transferring a gene from the paternal chromosome to the maternal or vice versa; the observed results are the genetic phenomena of linkage and crossing-over, which make possible the location of genes upon the chromosomes and the construction of chromosome maps. Should crossing-over take place between part of the Y-chromosome and part of the X, there should exist genes which may be located upon either chromosome and the genetic result would be partial sex-linkage, a trait so determined displaying an incomplete association with sex in contrast to the complete association characteristic of genes exclusive either to the X or to the Y chromosome. Koller and Darlington³ having observed crossing-over between portions of the X and Y chromosomes of the rat, Haldane⁴ made a search for partial sex-linkage in human records, for far more genes are known in man than in any other mammal. His search was rapidly rewarded. A fortnight's work revealed very strong evidence of partial sex-linkage in the case of three abnormalities: xeroderma pigmentosum, complete colour-blindness, and recessive retinitis pigmentosa unassociated with deafness. In three other instances there was good evidence for this mode of transmission—namely, some dominant pedigrees of retinitis pigmentosa, Oguchi's disease (a form of night-blindness), and recessive dystrophic epidermolysis bullosa.

The genetic results of partial sex-linkage can be detected only in the transmission of genes by males. The partially sex-linked gene must be situated upon an X-chromosome in the female, and crossing-over merely transfers it from one to the other without altering any ratios. A male bearing such a gene, however, carries it on his X-chromosome if he received it from his mother and on his Y-chromosome if he received it from his father. Crossing-over transfers the gene to the other chromosome, but will commonly occur in a minority of

¹ *Inherited Abnormalities of the Skin and Its Appendages*. London: Oxford University Press, 1933 (p. 382).

² *J. Genetics*, 1934, 29, 159.

³ *Ann. Eugenics*, 1936, 7, 28.

⁴ *Ann. Eugenics*, 1936, 7, 28.

ases only. Consequently a male who receives such a gene from his mother passes it on to more than 50% of his daughters and to less than 50% of his sons; this is reversed if he receives it from his father. It will be noticed that the relation to sex is not a very obvious one, and it is not surprising that the peculiarity of the genetic ratios was not observed until Haldane made his deliberate search. Since the announcement of the discovery of partial sex-linkage various workers have tested other human records, though until recently with negative results. Two more instances have now been discovered: one by Haldane¹ himself, one by other workers. Haldane has shown that recessive spastic paraplegia is transmitted in this way, and Mather and Philip² have found it to be true also for certain records of the transmission of hare-lip and cleft palate. Haldane in his original paper was cautious. Although he regarded the evidence as extremely strong, he stated that he "would be the last to regard incomplete sex-linkage as an established fact." No other explanation of the findings has been put forward, however, and in view also of the further supporting evidence the existence of partial sex-linkage in the human subject must be regarded as reasonably certain. Haldane has thus made the first attempt to map part of a human chromosome, though naturally, in view of the imperfections of existing records, the actual cross-over values are somewhat tentative. The unpaired portion of the X-chromosome, too, lends itself to mapping. Genes situated upon it must be linked to one another. Usually this could not be discovered, because seldom indeed would two rare genes be found in the same family group. Red-green colour-blindness is, however, a relatively common sex-linked trait and can be used as a marker. Bell and Haldane³ have shown that the genes for colour-blindness and haemophilia are situated very close together on the X-chromosome, crossing-over between them being very rare. White⁴ has shown that sex-linked night-blindness with myopia is due to a gene widely separated from that for colour-blindness. So here, too, a beginning has been made.

Apart from man, only one instance of sex-linkage has, so far as we are aware, been described in a mammal. This is the well-known black and yellow gene pair in the cat. Only a female can carry both, so, apart from a very few exceptions probably due to chromosome abnormalities, tortoiseshell cats are always females. In man, however, it would not be difficult to compile a list of forty or fifty ordinary X-borne, sex-linked genes. It may be that man differs in this respect from the laboratory and farm mammals so far studied. On the other hand it may simply be that the number of genes observed in man enormously exceeds those observed in any other mammal. It is also well known that what is apparently the same condition may not uncommonly be due to the action of any one of a number of genes, so greatly increasing the actual number likely to be observed in the human subject. It has been pointed out that the striking nature of ordinary sex-linked transmission makes it especially likely that the pedigrees will be placed on record, so magnifying the apparent proportion of such cases. There is nothing striking or unusual, however,

about the pedigrees of partial sex-linkage. Do seven or eight examples discovered in a period of four years indicate that the sex-chromosomes of man are particularly rich in genes as compared with those of other mammals?—probably not, though it is clear that future work will have this and other interesting queries to answer. Undoubtedly the story of the genes of the human sex-chromosomes indicates very clearly that human genetics is far from being an unpromising field. Human material may present many difficulties, but in some respects, and particularly if records are carefully made and appropriate statistical methods employed, the human subject offers advantages shared by few other forms. In years to come the consequences, both theoretical and practical, may well be of great importance.

MENTAL DEFECTIVES IN THE ARMY

The advent of machines in modern war has not made the human factor less important. It is important in new ways as well as in the old. Courage alone is not enough. Even courage and machines together may not be enough unless care is taken to ensure that the man in the machine has the necessary aptitude for its manipulation. It is not an easy task to devise laboratory tests which will enable us to detect specific aptitudes and specific disabilities, although in peacetime much has been done, in this country mainly by the National Institute of Industrial Psychology, in the devising of vocational tests and their application to the vocational selection of employees for industrial plants. Admittedly the higher the task and the more it concerns executive action the harder it is to find appropriate tests, partly no doubt because temperamental factors, which are so much more elusive than intellectual ones, occupy a foremost place in the equipment of the successful executive. It will be remembered that in his lectures on the qualities necessary for good generalship Sir Archibald Wavell emphasized the need for "toughness." This is an example of the type of quality that is difficult to assess in the laboratory or consulting-room.

At the other end of the scale, however, the problem is notably less difficult. The last war showed well enough the danger of enlistment at random of the mentally defective. A considerable proportion of those who returned as mental casualties from their units at an early stage in their military career were found to be mentally defective persons, who at best were a danger in a negative way from their slowness of comprehension, and at worst were a positive danger from their tendency to panic. It is not difficult to eliminate the majority of such defectives, and indeed nearly all of them, by appropriate recruiting examination. Those who escape elimination at this stage can usually be detected by expert observers in the early stages of training. The saving is not only in the time spent in training such men, who learn more slowly than others and retard the training of the whole of the group to which they belong; they can also figure disproportionately on sick parade. Moreover, general mental instability often accompanies intellectual backwardness, so that disciplinary offences are disproportionately common among

⁴ *J. Genetics*, 1940, 40, 403.

defectives. An intelligence test on recruitment, by excluding the defectives, will also exclude a number of defectives and unstable people who might without it pass as normal, especially as they exhibit a glibness of speech which deceives the inexperienced.

Dr. Esher's valuable paper in the current issue of the *Journal* (p. 187) demonstrates the liabilities incurred by enlisting mental defectives, and brings out clearly the effects on the sickness rate of a unit of the inclusion of defectives. As he points out, illness is a natural refuge for them to seek. Fortunately, as Dr. Esher observes, the problem of their early detection is not solely a matter of the application of intelligence tests. The fundamental value of a good history is well shown here as in all clinical work. Inquiry into the school and work record will often reveal a state of affairs which indicates the desirability of referring such individuals for expert examination. The employment of psychiatrists at this stage of medical organization of the Services should prove a real economy in the long run, but in the absence of sufficient numbers of such specialists the question arises whether a group intelligence test should not be used as a routine in all recruits. There is good reason to suppose that a considerable proportion of defectives could be discovered in this way. Such group tests do not require for their administration the services of a highly trained specialist; intelligent personnel with some appropriate training could administer them, the assessment being left to the psychiatrists and trained psychologists. In this way not only could the militarily useless and the unstable types of defective be excluded, but the stable types of higher grade will be allocated from the beginning to the kind of work for which they are fitted. Clearly we should be as exact as we can in the employment of human material, even if our methods may seem to fall short in exactitude of the engineer's technique when he chooses material for his machines.

THE OXFORD ANAESTHETIC VAPORIZERS

For some time past the Nuffield Department of Anaesthetics has been investigating means whereby liquid anaesthetics may be administered without complicated or bulky apparatus and in known concentrations of anaesthetic vapour. The result of this work is published in four articles in the *Lancet* of July 19. In the first (Macintosh and Mendelssohn) are discussed the physical problems involved in administering the vapour of a liquid anaesthetic in any desired concentration. For example, 90 calories of energy must be furnished for every gramme of ether vaporized. In order to maintain a constant temperature of the liquid ether, heat must be supplied from an outside source at exactly the rate at which it is used in transforming the anaesthetic liquid to vapour. This is achieved by surrounding the ether container with two other containers: the intermediate one holds crystals (or "reservoir substance") which melt at a suitable temperature, and as a source of energy hot water is poured into the outside one. The heat absorbed in transforming the reservoir substance from the crystalline to the liquid state (i.e., the latent heat of fusion) provides a source of heat supply at a constant temperature—that of the melting-point of the crystals. The reservoir substance acts as a thermal buffer, taking up heat

at any higher temperature but releasing it only at the temperature of its melting-point. A thermometer is placed in the intermediate container, and a sudden fall in temperature shows that the molten reservoir substance has all recrystallized; this is a sign that hot water must again be poured into the outside container.

The second paper (Epstein, Macintosh, and Mendelssohn) describes the Oxford Vaporizer No. 1, which incorporates so many striking advantages that Lord Nuffield has decided to present a thousand for distribution to the Services. Here the reservoir substance is calcium chloride, which melts at 30° C. The liquid ether is maintained at this temperature, so that there is always a constant and high concentration of ether vapour available in the container. When the patient breathes, air is drawn in through a valve. By means of a mixing tap the air can now be diverted wholly or in part over the surface of the ether or be by-passed directly to the patient, who thus receives air only. The apparatus includes a lightly spring-loaded spirometer bag which is easily worked by hand. The air thus drawn in can be used instead of the bulky cylinders of gases in common use as a *vis a tergo* to carry the anaesthetic vapour to the patient. The economy in the transport of cylinders is one of the outstanding features of this apparatus. In the third paper Cowan, Scott, and Suffolk describe the Oxford Vaporizer No. 2, in which a cylinder of liquid ether is maintained at a constant temperature above the boiling-point of ether. By means of a pin valve ether vapour is released at any desired rate. The vapour passes through and is measured by a meter which is surrounded by a reservoir substance at a temperature high enough to prevent condensation. In a mixing chamber the ether vapour mixes with oxygen and, if required, with nitrous oxide, so that any desired strength of ether vapour is delivered to the patient. In the fourth paper Pask and Epstein discuss the performance of the vaporizers. They point out that the definite smooth control which the Oxford Vaporizer No. 1 affords gives the anaesthetist confidence in supervising less experienced helpers in the administration of anaesthesia to several patients in an emergency. It also seems to make the administration of light ether narcosis easier than with any other method known. It can be used, too, for analgesia. Warm ether vapour appears to be less irritating than cold, and experiments are being continued to see whether a humidifier should be incorporated. It is pointed out that the vaporizer should be useful in the physiological laboratory, where workers will be able to correlate their clinical findings with percentages of anaesthetic vapour being administered.

FOETAL ERYTHROPOIESIS

The discovery of the liver principle by Whipple and by Minot, besides producing a cure for pernicious anaemia, served as a stimulus to the study of erythropoiesis in the adult marrow. One of the cells to which attention was directed was the megaloblast. The term served for two different types of cell. Ehrlich¹ in 1909 applied it to a cell he had seen in the blood and bone marrow in pernicious anaemia and also in the human embryo. Sabin² in 1921 used it for a cell in the chick embryo. Ehrlich's cell was 15 to 20 μ in size, haemoglobinated, and with an eccentrically placed finely differentiated nucleus; Sabin's had no haemoglobin but was basophilic. Turnbull³ confined the term to the cell in the human embryo under 10 mm. long. This cell, he said, was large—about three times the size of a red cell—and was polychromatic or orthochromatic.

¹ *Die Anaemie*, by Ehrlich, P., and Lazarus, A. Part I, 2nd edition, 1909. Vienna and Leipzig.

² *Johns Hopk. Hosp. Bull.*, 1921, 32, 314.

³ Turnbull, H. M., in *The Anaemias*, by J. Vaughan, p. 20, 1936. London.

Israel¹ described the megaloblast series in human marrow from non-haemoglobinated forms to haemoglobinated types dependent upon the degree of maturity. Peabody² referred to a non-haemoglobinated basophilic type of cell in Addison's anaemia which was similar to the Sabin cell but pyknotic. It is unfortunate that American workers tend to apply "megaloblast" to the Sabin type of cell, whereas in Europe the Ehrlich type is meant. This confusion is due to some extent to the comparison of adult marrow types with embryonic types and not to differences between haematopoiesis in the human and haematopoiesis in the non-human. There have been few detailed studies of human foetal haematopoiesis. Knoll³ published some work on a number of human embryos in 1929, and Gilmour⁴ has recently given a full description of the development of the embryo, including many early types. For this purpose he has had access to Prof. J. E. S. Frazer's collection of embryos, including one about sixteen days old, probably slightly younger than the Peter's ovum, their lengths being up to 3 mm., 3 mm. to 12 mm., and over 12 mm. He describes the development of the cells before and after the development of the circulation and their appearance in the various foetal tissues. He finds that the haemocytoblast—first formed from yolk-sac vascular epithelium—could form all types of cell, though the particular type depended on the site. For example, in marrow every red and white cell type could come from the haemocytoblast. Erythropoiesis was never present in thymic tissue, and in embryos over 48 mm. long both erythropoiesis and leucopoiesis were entirely extravascular.

Gilmour describes two types of megaloblast—the primitive and the definitive. In embryos under 10 mm. long the haemoglobinated cell corresponded to the megaloblast of Turnbull, but after the 10 mm. stage the haemocytoblasts appearing in the liver produced a smaller type of cell. These he calls the definitive cells or family. The earlier ones, which are non-haemoglobinated and basophilic, he calls primary erythroblasts. These primary erythroblasts either may form normoblasts with pyknotic nuclei (the normoblasts acquiring haemoglobin and developing into erythrocytes), or may acquire haemoglobin very early while they still have large detailed nuclei—the cell so formed he calls a definitive megaloblast. These cells may reduce in size, the nuclei become pyknotic, and they develop into erythrocytes in due course. The definitive megaloblast is smaller than the primitive megaloblast, and has a smaller and darker staining nucleus. The two types of megaloblast seen, one after the 10 mm. stage and one before, are so different that it is a pity the term should be used in the description of both. Erythropoiesis in the foetus is more complicated than that in the adult marrow: the latter is related to the everyday work of clinical haematology. Two things seem to be indicated: first, there should be agreement between haematologists on nomenclature, and, secondly, further work is needed on foetal erythropoiesis by some method which utilizes living tissues (of the tissue culture type), so that the change from stage to stage may actually be seen taking place.

GARGOYLISM

The clinical picture in the bizarre combination of skeletal defects, cranial deformity, mental deficiency, spleno-hepatomegaly, and corneal opacification which goes under the name of gargoylism has become fairly clear from the large number of cases reported in recent years. That there is still much confusion, however, on a number of essential

features is reflected in the multiplicity of names for this condition. American writers speak of Hurler's syndrome, after Gertrud Hurler, who published an account of two cases in 1919. Priority has been claimed for Hunter, who reported the condition in 1917, and a more recent claim⁵ suggests that John Thomson of Edinburgh recognized it as early as 1908. Apart from eponymic designations, with their inevitable and rather futile controversies, the affection is also widely known on the Continent and in the U.S.A. under the name of dysostosis multiplex. None of the names is very happy, but more significant than the confusion in names is the confusion that prevails in the differential diagnosis from Morquio's disease. The two affections have dwarfing and a characteristic chondrodystrophy in common, and there are instances in the literature of fairly definite examples of both affections being reported under the wrong designation. In clear-cut cases the differential diagnosis presents no difficulty, for in Morquio's disease the head is normal and there is no mental deficiency. Ocular changes of an indefinite type have been reported in this disorder,⁶ but the characteristic cloudiness of the cornea appears to be absent. It is also said that the skeletal anomaly is more severe in Morquio's disease than in gargoylism. But the confusion may perhaps reflect not error but a fundamental unity between the two syndromes. In the elucidation of a recently recognized syndrome only the extreme cases are studied, and it may well be that what are now regarded as two distinct affections may represent two extreme limits of a continuous one. Such a view, which appeals because of its simplicity, does, however, require evidence which is not yet forthcoming. In none of the familial groups so far reported has there been enough dissimilarity in the different members of the family to warrant anything but one diagnosis (though this may be due to the "familial stamp" so characteristic of hereditary affections). Moreover, there is pathological evidence that gargoylism is a lipid dystrophy of the Tay-Sachs type, and there is no such evidence for Morquio's disease. It would be well if future studies on the subject were to take this possibility into account.

PSYCHOLOGY AND THE "HARD CORE"

One of the most difficult tasks of voluntary mental health work is to place discharged patients in suitable employment. Some of these patients, from their inability either to find work or to appreciate which work suits them, relapse and sink into depression, and return again and again for treatment. Early in 1939 the Mental After Care Association started an employment department under Miss Kathleen Laurie, a trained psychiatric social worker with knowledge of the various problems of employment, and the report⁷ for the first eighteen months reflects considerable success for the experiment. Although much of the work was done during the war, 482 persons out of 666 were found employment, and some of the remainder obtained posts for themselves. Domestic service absorbed the largest number: next came clerical work and then engineering. Some good openings were found in sales departments, in needlework, and on the land, but Miss Laurie and her co-workers received more requests for workers in hospital linen rooms and on the land than they could find. Engineering was a good outlet, and the department was in close touch with a number of staff managers who were sympathetic with its aims. Of patients placed for the first time only twenty women and seven men failed—eight

⁷ *Employable or Unemployable?* 1941, Mental After Care Association.

of the women with relapses; and of the total number for whom employment was found one-quarter were "very successful." Twenty-eight patients were given training in various kinds of new work. Co-operation between such a department, the patient, and the employer is, of course, essential in work of this kind, and depends largely on the head of the department: the more help she can command the more successful she is likely to be. Miss Laurie sought the help of clubs, churches, and private friends in protecting the patients from loneliness and encouraging their special interests, and the co-operation of hostel wardens in finding homes offering some social life, or the necessary control for the unpunctual or the alcoholic. At times she persuaded insurance societies to pay health benefits to patients who had been unable to notify their illness at the proper time. She was on friendly terms with innumerable employment agencies. Much of her work was the tactful education of all kinds and conditions of people about the facts and effects of mental disorder and the capacity of patients to recover. It was especially difficult to bring home to them the need for speed, and official delays caused hardship. She concludes that the "hard core" of unemployment could be considerably reduced by a service of this kind on a larger scale, and that the work should be put into the hands of trained workers attached to a Government Department, the Unemployment Assistance Board, or a voluntary association subsidized and given facilities. One of the most surprising things in the report is in the foreword by Miss E. D. Vickers (until recently secretary of the Mental After Care Association), which states that this work has had to be abandoned owing to war conditions and financial stress. If any activity ought to be continued it is, surely, this successful work among one of the most expensive and useless classes of society. These persons cost millions of pounds in health and unemployment insurance and in unemployment assistance, in accommodation in mental hospitals, poor-law institutions, and prisons. Let us hope that Miss Laurie's work will be resumed and expanded at the earliest possible moment.

LANATOSIDE C (DIGILANID C)

The glucosides of *Digitalis lanata* were first used medically in this country a few years ago, digoxin becoming rapidly established as a valuable new drug. The chemistry of these glucosides was worked out by Stoll, and lanatoside C was found to differ considerably from the other glucosides of *Digitalis lanata* and *purpurea*. Fahr and LaDue¹ tested the therapeutic action of lanatoside C (or digilanid C) upon 256 patients with heart disease, and found that it had a rapid and efficient clinical action. Intravenous administration of 1.6 mg. reduced the heart rate to 85 or lower in fifty-two cases, the response being achieved in under two hours in thirty-eight cases. Oral administration, first of 3.75 mg., then of 2.5 mg., within twelve to twenty-four hours reduced the heart rate to less than 85 in all cases within forty-eight hours. The rate of clearance of lanatoside C, which was estimated by stopping the administration and measuring the time until the pulse rate rose above 90, varied from seven to twenty-one days, with a mean of twelve days. This approximates to the results reported by Robinson for *Digitalis purpurea*. The authors found that the drug was efficacious in the treatment of congestive heart failure with normal sinus rhythm, and would often restore rhythm in cases of supraventricular flutter. They concluded that lanatoside C was less toxic than preparations of *Digitalis purpurea*. Nausea and vomiting were rare,

and when these occurred they were usually transient. This report confirms the general opinion that the clinical value of the glucosides of *Digitalis lanata* is high.

CHEMISTRY OF DIARRHOEA AND VOMITING

It is increasingly recognized that the syndrome of gastro-enteritis in infants is something more than a local lesion of the alimentary tract, and that treatment to be effective must take note of the profound changes produced in the whole of the infant's tissues. Broadly speaking such changes may be summarized by the word "dehydration." In a series of fifty-one infants A. G. V. Aldridge studied the indications for giving fluid by routes other than the mouth, the best form of fluid to use, the route by which it should be given, and the value of haematological and biochemical examination in forming a decision as to the most suitable fluid to use. His paper¹ is concerned with the last but one of these. The majority of the infants were suffering from gastro-enteritis and a few from pyloric stenosis. The investigations carried out on the blood comprised red cell counts, haemoglobin estimations, haematocrit readings, and the estimation of plasma chloride and plasma protein concentrations. For these purposes very small amounts of heparinized blood (less than one-third of a cubic centimetre) were collected in specially designed tubes from the subject's heel or leg. The characteristic features of dehydration are described under three headings: clinical, haematological, and chemical. Discussing the blood findings, Aldridge notes an increased red cell count, haemoglobin concentration, and haematocrit readings indicating haemoconcentration. But there are certain special features of infancy which make the interpretation of blood investigations particularly difficult. For example, the red cell count normally alters so much during the first six months of life that reference to a special series of normals is essential. Thus a red cell count of 5.5 millions per c.mm. is normal in an infant of 4 weeks of age, but represents a fair amount of dehydration in an infant aged 3 months. With haemoglobin estimations a similar difficulty arises; some degree of hypochromic anaemia may be present, and in actual practice estimations of haemoglobin alone (so useful in adults with dehydration) gave an inadequate indication of haemoconcentration. Aldridge likewise finds that with haematocrit readings the age of the infant, and hence the normal for age, have to be taken into consideration. With this sort of special standard he found a noteworthy increase above the normal in dehydrated infants as shown by this test. For the chemical features of dehydration he studied the plasma chloride and plasma protein. For the former he found figures considerably higher than normal in infants with gastro-enteritis, but the height of the plasma chloride did not necessarily vary with the degree of dehydration or with the clinical condition of the patient. This is because there are various factors concerned with the chloride content of the blood such as loss of sodium chloride in the stools in diarrhoea and renal insufficiency leading to an accumulation of chloride radicles. In pyloric stenosis the chlorides show an almost distinctive variation owing to the loss of hydrochloric acid and sodium chloride in the vomit, so that in infants with this complaint dehydration and haemoconcentration are actually associated with a low blood chloride. Plasma chloride in gastro-enteritis was on the average a little higher than in a series of normal infants, but such a rise could not be used as an index of the state of hydration in the circulating blood. Aldridge is applying these results to the solution of other parts of his investigations—namely, what fluid to use, how to give it, and when.

DEATHS ON THE TABLE IN GENERAL PRACTICE

BY

JOHN ELAM, M.R.C.S., L.R.C.P.

The harrowing experience of a death on the operating table comes sooner or later to every anaesthetist, and it is to be regretted that the subject is not more freely and frankly discussed in medical literature and at medical meetings.

We must admit, I suppose, that anaesthetic deaths are avoidable and should be avoided. In the *British Journal of Anaesthesia* (1937, 14, 55) Dr. H. Grant-White discusses how some deaths may be avoided, and he stresses particularly the need for modification in the method of inquiry into anaesthetic deaths, which would result in the collection of valuable information. The same journal in an editorial (1938, 15, 86) suggests that the cure for anaesthetic fatalities is education and more education. We cannot, however, obtain this education unless anaesthetists will tell us about their own cases.

The following cases occurred in my own practice, and their publication will, I hope, lead to the recording of similar fatalities by others.

Illustrative Cases

Case 1.—A woman aged 32, admitted to hospital with a diagnosis of ruptured ectopic gestation. This patient was extremely ill and almost pulseless. Premedication: atropine, grain 1/100. Induction: gas-oxygen-ether; a nasal tube was then introduced into the trachea and the anaesthetic was continued with gas-and-oxygen. When the patient was being got ready for operation there was some little trouble in adjusting the table, and I assisted in getting it put right. Just at this moment the patient stopped breathing, and although oxygen was administered through the endotracheal tube and cardiac massage was adopted she died.

Case 2.—A man aged 75. Operation: removal of prostate. No premedication. I was not present in the theatre at first, because the surgeon intended to give a spinal anaesthetic himself. The patient, however, had a very marked osteo-arthritis of the spine and the needle could not be introduced. I was sent for in a hurry to administer an inhalation anaesthetic. Gas-oxygen-ether was the anaesthetic used, and all went well until the surgeon had almost removed the prostate, when the patient stopped breathing. An attempt was made to give artificial respiration, but the chest wall was absolutely rigid and artificial respiration had no effect. An endotracheal tube was introduced and oxygen given under pressure. The patient's colour did not improve, and as no pulse rate could be found cardiac massage was undertaken. After the second "squeeze" of the heart this started to beat again, and the patient's condition improved and respiration was re-established. The patient died twenty-four hours later without having regained consciousness. Post-mortem examination showed minute haemorrhages on the surface of the brain.

Case 3.—Child aged 10 with a badly crushed foot, in which gas gangrene had developed. The child was terribly ill, but at the parents' urgent request it was decided to amputate. Premedication: morphine and atropine. Anaesthetic: gas-and-oxygen. During the operation the patient's condition became worse and worse, and just as it was completed the child died.

Case 4.—Child aged 6. Intestinal obstruction—general peritonitis and appendicitis. Premedication: atropine. Anaesthetic: gas-oxygen-vinesthene. All went well until the surgeon started to stitch up the peritoneum, when the patient developed violent ether convulsions. Oxygen was administered and the patient's condition gradually improved, the convulsions passing off in about ten minutes. After the operation was completed oxygen was administered for some little time, as I feared that the convulsions might start again when the patient returned to the ward. After half an hour, as the patient's colour was good and

the general condition fair, I told the porter to fetch the trolley to take the child back to the ward. Just as the trolley was brought alongside the table the patient died.

Case 5.—Child aged 4. Acute peritonitis and appendicitis. Anaesthetic: gas-oxygen-vinesthene. All went well until the surgeon introduced his hand into the abdomen. Immediately there was a violent regurgitant vomiting of the stomach contents: it was just like pouring water out of a jug. I tried to mop out the mouth and introduce an endotracheal tube, but failed completely. The patient died in a few minutes.

Case 6.—Man aged 85. Acute retention of urine. An emergency operation for the introduction of a suprapubic tube. The patient's condition was not good and I was asked to give only gas-and-oxygen. He had, however, received no premedication and the operation presented unexpected difficulties. I pushed the gas a little too far; the patient became anoxaemic and stopped breathing. An endotracheal tube was quickly introduced and oxygen given under pressure. The patient started to breathe again and the operation was completed, but he died six hours later.

Case 7.—Girl aged 15. Acute appendicitis, first seen at 3 p.m. She was the child of most difficult parents, who insisted that she must not be removed to the nursing home until the surgeon arrived. The nursing home was next door. It was impressed on the parents that no food of any kind must be given. About five o'clock, however, the girl felt better and demanded a meal. She was given a large feed of sausages, of which we were not informed. The operation took place at seven o'clock and proved to be one of exceptional difficulty. Endotracheal gas-oxygen-ether was the anaesthetic administered. Just as the surgeon was about to stitch up the peritoneum ether convulsions developed. These, however, passed off in about ten minutes, and the patient's condition improved. The endotracheal tube was withdrawn and the patient was returned to bed. She died early the next morning without recovering consciousness.

Case 8.—Boy aged 15. Multiple injuries from road accident. Anaesthetic: gas-oxygen-vinesthene. It took a long time to repair the many injuries, and the boy's condition became worse and worse. When the operation was completed he was almost pulseless, and died twenty minutes afterwards.

Discussion

Now, I think something may be learned from this series of cases. Some of these deaths might have been avoided.

In Case 1 I should never for a moment have taken my eyes off the patient. In Case 2 I think I hurried the induction too much and should have passed the endotracheal tube immediately breathing stopped instead of trying to do artificial respiration on an impossible subject. Cases 3, 4, and 8 were beyond my powers to save. In Case 5 death should have been avoided. I should have been ready for the vomiting and should have passed the endotracheal tube and washed out the stomach in the ante-room before the patient went on to the table.

Case 6 was an example of how dangerous it is to try to do too much with gas-and-oxygen. Had a little ether or vinesthene been added to these gases a successful result to the operation might have been expected. The cause of death in Case 7 was really, I think, the sausages, and is an example of what may happen when a patient is left in the care of untrained people for some hours before operation.

To ensure the proper after-care of children who have received in-patient treatment for injuries due to enemy action, the Ministry of Health is arranging for E.M.S. hospitals to notify the Medical Branch of the Board of Education (at Branksome Dene Hotel, Bournemouth) whenever it is proposed to discharge a child casualty. The Board of Education will then get in touch with the local or welfare authorities in the area to which the child is to be sent. Circular 2427 of the Ministry of Health prescribes the form of notification, and asks hospital authorities to bring these arrangements to the notice of medical superintendents and other medical officers concerned.

INCIDENCE OF VENEREAL DISEASES

Since the outbreak of war the incidence of venereal diseases has not increased to anything like the extent that was feared. At a discussion on this subject arranged by the Medical Society for the Study of Venereal Diseases on July 26 the unanimous view was that while there had been some increase it was very slight as compared with the experience of previous wars.

The figures given showed some rise in the number of early cases of syphilis; the figures for gonorrhoea are more difficult to assess. Statistics given by the medical officer of one clinic, while they showed an increase in syphilis, showed a decrease in gonorrhoea, but the latter he attributed to the fact that many more cases of gonorrhoea are now treated outside the clinic by general practitioners. With regard to the Army, of course, it would be fallacious to compare pre-war ratios with those obtaining to-day. The pre-war Army was a professional one, consisting almost entirely of young unmarried men, whereas we have now a citizen Army which includes large numbers of men of middle age and married men, and the outlook would be depressing indeed if the incidence in the Army to-day were not much lower than in peacetime. One Army medical officer said that he thought the more favourable position was due, first, to the lower incidence of venereal diseases in the civil population, thanks to the work of the clinics; secondly, to the greater effectiveness of modern remedies; and, thirdly, to the fact that the present-day soldier is less promiscuous than his predecessors—not that he is more continent but that he distributes his favours less widely. This officer said that a very small proportion of Army infections—6%—were due to professional prostitutes, 80% to amateurs, and that the rather surprising proportion of 14% were marital in origin. A naval medical officer stated that naval ratings were now well instructed in venereal diseases, and the sailor who exposed himself recklessly under the influence of alcohol was rare. In most cases the pros and cons had been carefully thought out, and any subsequent venereal infection came as a surprise; it was due to misplaced confidence in the female partner. This officer said that over 90% of the naval cases were traceable to amateurs; in one port only 3% were traced to professional prostitutes.

Women's Services and Reception Areas

The ratio of gonorrhoea to syphilis in the Army was given as round about 8 to 1; one officer of the Royal Air Force mentioned a figure of 13 to 1. All the speakers agreed that in the women's Services the incidence of venereal diseases was negligible. A medical officer of the W.R.N.S. said that only half a dozen infections had been discovered in a personnel of 16,000. A woman medical officer of a clinic in Hertfordshire said that during the eighteen months that the clinic had been opened there had been only three women Service patients. This officer went on to say that it had been anticipated that among the evacuees from London invading Hertfordshire there might be a good deal of infection, but in fact such cases among the evacuees had been very rare, and the infections which had to be dealt with were among the native population, where there were a good many cases of old neglected syphilis, either acquired or congenital, with a few recent infections. A number of wives of Service men also came to the clinic—unsophisticated women in great distress—because their husbands, on the instruction of the regimental medical officers, had written to them saying that they (the husbands) had been discovered to be infected, and advising the wives to undergo examination. This woman officer strongly protested against leave being given to Service men while they were under treatment or observation for acute gonorrhoea. On the other hand, an R.A.F. officer urged that curtailment of leave after venereal disease had been contracted would lead to concealment, and that, having regard to the efficacy of modern treatment, the case which was in an infectious stage when it left the Service clinic was so rare that it might for practical purposes be discounted.

Control of Prostitution

Colonel L. W. Harrison, who presided over the discussion and opened it, said that a suggestion had been made that owing

to the largely urban distribution of clinics many rural cases must go untreated. If that had been so, however, syphilis would have become common in rural areas, but although those areas had now been infiltrated with Service personnel and evacuated people there was no indication whatever that they had been found to be rife with venereal disease. He gave some figures showing the incidence in England and Wales which indicated that although there had been some wartime increase the incidence was lower than it was seven years ago, and there was nothing like the position, present or prospective, which obtained in 1920.

The chief point of controversy at the meeting concerned the advisability of compulsory measures against the recalcitrant contact. A woman medical officer said that some low-class amateur prostitutes still seemed to flourish, and she urged that in wartime the activities of such antisocial persons should be forcibly restricted. It appeared, indeed, to be the majority feeling at the meeting that some measure of control was called for, but the meeting was reminded of the unfortunate experience of the last war in this respect, of the probable public outcry if there was discrimination against the female partner, and of the dangers of malicious accusation and the like, and there was not a near enough approach to unanimity to make it seem advisable to send a resolution to the Government.

AWARDS FOR GALLANTRY IN CIVIL DEFENCE

The award of the M.B.E. (Civil Division) to Dr. ISOBEL ORD MACALISTER, Civil Defence Medical Service, Wallasey, and the George Medal to Dr. PERCY GILBERT HORSBURGH, First Aid Area Commandant, A.R.P. Casualty Service, Nuneaton, is announced in a *Supplement to the London Gazette* dated July 25. The announcements read as follows:

Dr. MACALISTER: "During an air raid high-explosive bombs were dropped close to a first-aid post to which a large number of casualties had been brought in for treatment. Severe damage was caused, and the supplies of electricity, gas, and water were cut off. Dr. MacAlister was flung bodily across the ward by blast from the explosion. Broken glass and debris littered the floor and the building was in darkness. Dr. MacAlister, although herself injured, was not deterred from her work and, by the light of hand torches, she continued to attend to the wounded in a cool and collected manner. During this time bombs were falling near by. Dr. MacAlister's courage was an inspiration to the staff of the post and encouraged them to carry out their duties during the night."

Dr. HORSBURGH: "Throughout an air raid Dr. Horsburgh, with complete disregard of his personal safety, engaged in the rescue of persons trapped in the debris of bombed buildings and in giving medical attention to the wounded. He personally sought out and reported many of the incidents and procured the necessary assistance from the rescue and casualty services. On one occasion Dr. Horsburgh personally conducted rescue operations and crawled through the ruins of houses to rescue three people from the debris. He also succeeded, with assistance, in recovering alive a man who had been buried for more than twelve hours. Dr. Horsburgh's work was carried out in circumstances of great and continuous danger from high-explosive bombs and damaged buildings, and his gallantry and devotion to duty were an inspiration to the personnel of the local civil defence services."

T. H. Tomlinson, jun. (*Publ. Hlth. Rep.*, Wash., 1941, 56, 1073) records an outbreak of psittacosis among birds in the National Zoological Park at Washington, D.C., in January and February, 1941. Fifteen birds positive for psittacosis were discovered among sixty dying or killed during the epizootic. These consisted of twelve parrots, both South American and African, one finch, and two African doves. Two of the eight bird-house employees developed clinical psittacosis and recovered. No cases were reported among the general population.

Correspondence

Depressive States in the Soldier

SIR.—I have read with interest Captain R. F. Tredgold's article (July 26, p. 109) upon depressive states in the soldier. It appears that such reactions may prove to be the most typical psychological disturbance of this war, just as the anxiety hysterics were of the last. If this is so, we may gain valuable information concerning the exogenesis of depression. I myself am not in a position effectively to speculate about the different psychological reactions to the two wars, but it would seem plausible that the lack of any real possibility of retreat from the front line to safety in this war may be an important factor.

It seemed to me unfortunate that in a clinical study of depression of the type here described the old bog of the neurosis-versus-psychosis argument should have been allowed to occupy so much space. This argument as it is generally formulated is particularly sterile and time-wasting, leading as it does away from the accurate study of the individual case towards what Meyer has termed "the arch sin of modern psychiatry—that is, blinding oneself to the specific facts of the case at hand by asking at once, 'Is it a major psychosis?' " I do not think that Captain Tredgold has fallen into this error in his own clinical presentation, but in making reference to a recent paper of mine (*J. ment. Sci.*, July, 1940) he attributes to me, directly or by inference, views which I emphatically do not hold. Thus he suggests that I make a sharp distinction based upon one criterion between neurosis and psychosis, each again subdivided into anxiety and depressive states. He goes on to state that its use (that is, of such a distinction) was justified (by the authorities quoted, including myself) in that it indicated also a complete distinction of treatment and prognosis. In the paper under review I put forward the view that a distinction between psychosis and neurosis based upon the relationship with external reality of the patient's symptoms was useful and valid. I expressly stated that such a distinction could not provide a sharp dividing-line between neurosis and psychosis, and that differences in treatment, though important, could be exaggerated. Lastly, I mentioned my inability to differentiate between anxiety and depressive states.

In my opinion much of the controversy which has arisen over this matter has been due to the adoption of an absolutist standpoint by one or other party. It is as wrong to assume a sharp cleavage between the two conditions as it is to deny the distinction altogether. Seldom in human biology are such clear-cut differentiations to be found, but this is the poorest possible argument for the abandonment of the conception of the affective neurosis. There is a world of practical difference between the normal individual who is mourning the death of a close relative and the manic-depressive in his fifth or sixth attack of depression, the aetiological factors of which may escape a careful psychiatric history taking. Yet a graded series of cases could certainly be produced running from one end of the scale to the other: from what one may term the normal through the neurotic to the psychotic. At one point in the series it would be possible to say, "This patient's mood change is related in an orderly manner to the logical problems of his environment"; at another point this would no longer be true: between the two would be found cases where a differentiation would be a waste of time.

To a psycho-analyst, perhaps to a biochemist, searching the cases for some special facts the whole grading might be irrelevant, but to the clinician it remains of great practical importance. I do not think that Captain Tredgold's paper, concerned as it is with the admissions to a hospital for psychotics, throws much light upon this particular problem.—I am, etc.

C. H. ROGERSON,
Medical Director.

Cassel Hospital, July 30.

SIR.—Captain R. F. Tredgold's topical paper (July 26, p. 109) stirs up interesting questions which merit thrashing out.

1. Does a psychosis differ in any essential feature from a psychoneurosis, and, if so, in what? Those who have had experience in closely studying mentally afflicted patients are. I

think, mostly agreed that there is no hard-and-fast line between the two disorders, but I would suggest that a factor of crucial importance running through the series is the degree and type of "insight" present at any given moment. The psychotic individual has no insight of either type. Once he acquires intellectual insight he, although possibly disordered in mind (a borderline case, perhaps), is not insane. Intellectual insight, however, is not enough, and a patient only recedes from the borderline in proportion as he gains "affective" insight. In the early stages of the process he is a psychoneurotic, but approaches more and more to that scientific abstraction which we call "the normal" as his affective insight increases.

2. It would seem a truism to say, as does Captain Tredgold, that "any state of depression is the result of the interaction of external factors upon a personality." Often, however, the so-called external factors are fictitious. A man most dreads what he imagines may happen, not what actually has happened or is happening. Of course, as an external world does exist, some scapegoat can always be found therein to carry what Captain Tredgold labels "external factors."

3. As regards treatment by "prolonged narcosis," this has come to seem to the writer, whose experience recently has been so largely with those neurotics who resort to alcohol, to be nothing other than the medical equivalent of a good "bout." As argued in a paper entitled "Paraldehyde Addiction" (*Brit. J. Ineb.*, 1934, 31, No. 3), many alcoholists resort to paraldehyde in an attempt to cure alcoholism, which itself resulted from an attempt to cure depression. Truly we can learn from our patients. We might learn what to avoid as well as when to copy. "Bouts" of narcotic substances are not good for shirking neurotics, who have in all probability self-administered that sort of medicine before ever they had to see a doctor.—I am, etc.

Caldecote, July 27.

A. E. CARVER.

Functional Dyspepsia

SIR.—In his paper on the incidence of dyspepsia in a military hospital (July 19, p. 78) Major J. H. Hutchison remarks upon the low incidence of neurosis in his cases as contrasted with the "remarkably high proportion" of cases quoted by Saffley (11.2%). He then mentions that in his in-patient group there were 28.4%, and in his out-patient group 43.6%, of cases classifiable as functional dyspepsia, the chief cause of which he concludes to be worry and anxiety, although he does not regard these men as cases of anxiety neurosis.

Attention is not drawn, however, to the fact that in Saffley's group the diagnosis of anxiety neurosis was made by psychiatrists, to whom the majority of cases showing no radiological abnormality were sent. Thus most of Major Hutchison's groups of functional dyspepsias should have been investigated psychiatrically for a valid comparison; and, from what he states, a high proportion of these soldiers would have been labelled "anxiety neurotics" by a psychiatrist. He makes the diagnosis of psychoneurosis in a few cases showing gross emotional disturbances—quite uncommon features of the average anxiety neurosis—then rejects the diagnosis of anxiety neurosis in the functional dyspepsia groups because there was an "adequate cause" for their worry, which was not of "pathological intensity."

There is surely some confusion here. The "adequate causes" are factors operating on all soldiers, so there arises the problem of the predisposing factor. Major Hutchison answers this by introducing the vague concept of an "autonomic nervous system which is constitutionally somewhat precariously balanced." But is this unsatisfactory explanation necessary? Men who worry to such a degree as to produce dyspepsia "over the fate of relatives in bombed areas or in the unfamiliar surroundings produced by evacuation, or over the uncertainty of future movements," are obviously prone to abnormal anxiety. The author does not appear to have investigated the previous psychological histories of these men. Consequently he misses what, from our experience, would have been their outstanding feature—namely, that they are chronic worriers, or, in other words, anxiety neurotics. Naturally more anxiety is aroused when the external situation is more exacting, but the essential point is that the predisposition is a personality factor which can be understood in psychological terms.

Functional dyspepsia is thus a manifestation of an anxiety neurosis since it is a functional nervous condition produced by anxiety—and anxiety neurosis seems to us a preferable term since it indicates the aetiology and treatment.—We are, etc.,

Hyperventilation Tetany in Tropical Climates

SIR.—Surgeon Lieutenant-Commander Forbes Guild's letter (July 26, p. 138) serves the very useful purpose of emphasizing the commonness of "fireman's cramp" under certain conditions of high temperature. There is, however, a clear differentiation between cramp and tetany. The experimental work which I quoted in my short paper showed that true tetany has been produced as a result of prolonged exposure to a high temperature in a hot bath. The conditions in a hot bath are simulated in nature only when a high temperature coincides with a high humidity, and it is in such conditions that the accessory cooling mechanism of over-breathing is called into action. Even when the required conditions prevail, only those persons who are sensitive to hyperventilation will develop tetany. The sensitivity of my patient was proved beyond all doubt.

"Fireman's cramp" can affect anyone who perspires freely over a long period, and, so far as I am aware, does not depend upon any personal idiosyncrasy. My patient, who was a very intelligent man, was quite certain that the tetany produced by over-breathing was identical in every respect with the attacks which he had had in tropical climates. I feel confident that a proportion of the cases which are loosely called "fireman's cramp" are, in fact, manifestations of tetany.—I am, etc.,

London, W.1, July 29.

ALEC WINGFIELD.

Anatomical Nomenclature

SIR.—Anatomy is the foundation of medicine. Each of us should have a profound knowledge of it. The memorizing of thousands of names of structures, as well as remembering their relative positions, throws a great strain upon memory and imagination even when each structure has one name. The old nomenclature, exclusively used before 1895, was heterogeneous, as it included the names of anatomists, surgeons, and mythological characters.

In 1895 the *Basle Nomina Anatomica*—an attempt to improve the old nomenclature—was published. This contained a great many new names, replacing names in the old nomenclature. Many of these new names were better than the old names; many others, however, had no advantage over the old ones; while still others were definitely worse. The effect of the publication of the *Basle nomenclature* upon the teaching of anatomy in this country was appalling. Most universities and medical schools taught the old nomenclature, and many of them still do so; others taught the *Basle names*; and most doctors had some knowledge of the *Basle names*, but kept to the old nomenclature. In 1909 *Gray's Anatomy* adopted the *Basle names*, and after this the books on surgical anatomy and anatomy were written in the old nomenclature with the *Basle names* in brackets; while a few were written in the *Basle nomenclature* with the old nomenclature in brackets. Thomson and Miles's *Manual of Surgery* adopted the *Basle names*, but nearly all surgical books were, and still are, written in the old nomenclature.

This unsatisfactory state of things continued till 1933, when the Anatomical Society of Great Britain and Ireland published the *Revised Basle Nomina Anatomica*, or Birmingham notation. This retains the best names in the two previous notations, while all the new names have been chosen carefully and are generally self-explanatory. It is a simple matter for anyone knowing the old notation to master the Birmingham notation.

It is an encouraging fact that the last edition of *Gray's Anatomy, Descriptive and Applied*, and of *Cunningham's Text-book of Anatomy* are written in the Birmingham notation with the *Basle names* in brackets.

If a small book containing the old nomenclature, the *Basle nomenclature*, and the Birmingham notation were sent to every medical man, and if the Birmingham notation were taught in all universities and medical schools, the present intolerable muddle would end in a year or two. At the present time a student

buying the newest books on surgery, anatomy, and surgical anatomy will probably get *The Operations of Surgery*, 1937, by Rowlands and Turner, written in the old notation; *Cunningham's* or *Gray's* textbook of anatomy, 1937 and 1938 respectively, both written in the Birmingham notation; and *Callander's Surgical Anatomy*, 1939, written in the *Basle nomenclature*. In studying hernia he will read of the external and internal abdominal rings and of Gimbernat's ligament in the surgical book; the anatomy book will describe carefully the superficial inguinal ring, the deep inguinal ring, and the pectineal part of the inguinal ligament; and, to help him still further, the surgical anatomy book will call the same structures the subcutaneous inguinal ring, the abdominal inguinal ring, and the lacunar ligament. This sort of thing continues right through each book. These are most excellent books; if the surgical and surgical anatomy ones were written in the Birmingham notation, as *Gray's* and *Cunningham's* textbooks are, it would be a pleasure to read them, making one supplement the other. As it is, it is maddening even with the help of bracketed words.

If the Birmingham notation were alone used thousands of useless names of structures would be discarded, and every student of anatomy would get rid of a heavy incubus.—I am, etc.,

Bridgwater, Somerset, July 17.

JOHN H. AYTOUN, M.D., C.M.

Insulin and Diabetic Coma

SIR.—On the subject of diabetic coma Dr. Leslie Cole (July 26, p. 137) states: "With regard to insulin dosage it is very difficult to lay down rules and perhaps it is unwise to try." The following was worked out at the Montreal General Hospital, and when it was explained to me they added that it was fool-proof. The degree of coma varies from mild to profound—in profound there would not be the slightest response to a pin-prick.

The plain insulin is given intravenously, immediately followed by the same amount subcutaneously, and that in turn followed by double the amount of the protamine-zinc-insulin subcutaneously. The result of the intravenous insulin is that the patient snaps out of the coma. The subcutaneous insulin comes into play a little later, while the protamine-zinc-insulin comes into action still later and has a prolonged action. The second half of this treatment follows when the patient comes to; it consists of 20 grammes of carbohydrate every thirty minutes in the form of orange juice. In practice it simply meant that the patient had the juice of two oranges with 2 oz. of sugar every thirty minutes. A pitcher of orange juice was made up and the patient took the required amount every half-hour for a day or two until his diet and insulin were worked out. Since oranges are unobtainable the 20 grammes of carbohydrate every thirty minutes could be made up of something else, but from the results shown me I would suggest the method be given a trial.

Degree of Coma	Plain Insulin		Protamine-zinc-Insulin: Subcutaneous
	Intravenous	Subcutaneous	
Mild	25 units	25 units	50 units
Moderate ..	50 "	50 "	100 "
Severe	75 "	75 "	150 "
Profound ..	100 "	100 "	200 "

—I am, etc.,

Clapham, S.W.4, July 26.

Brucella abortus Infection responds to Sulphapyridine

SIR.—When a person is infected with *Brucella abortus* he is condemned, as a rule, to a prolonged illness which may not be diagnosed for some time and for which there has been no specific treatment. The subject of this note has been more fortunate than the average, and the case demonstrated the potency of our newest bactericide.

An enthusiastic Home Guard aged 42 took part in a prolonged exercise on Sunday, July 6: the sun was very hot and he had no protection but a "footling forage cap." On that evening he had a headache, fever, and was sick. When he was seen the following day it was decided that he had "sun fever," and was kept in bed on a liquid diet, with salicylates for relief of headache. After a week in bed his headaches had subsided suffi-

ciently to allow him to read; during the greater part of the day he was comfortable, but by 7 p.m. (new Summer Time) he was very feverish and miserable. During each night he sweated profusely and drenched his bed-clothes; by morning he was subnormal and fairly comfortable.

On July 16 he was running an evening temperature of 103° F., dropping to 98° F. by morning; he was constipated, but otherwise felt moderately well. A statement that he felt rather as he had done when he suffered from paratyphoid B in France during 1918 led me to take his blood for agglutination tests. At the same time he was given sulphapyridine, a total of six grammes being given within forty-eight hours. His temperature came down and remained down. On July 18 the report came back that his serum agglutinated *Br. abortus* (Bang) in a dilution of 1 in 500. On July 28 he is well and free from fever.

On inquiries being made into possible sources of infection the patient said that he never drank a glass of milk, which he took in his tea and, occasionally, with cereals. His milk came in a bottle labelled "pasteurized" from a good dairy. If this patient's response to sulphapyridine is not a mere coincidence we may congratulate ourselves upon having one more target for our new weapon.

My thanks are due to Dr. Cooper of the Dorset County Laboratory for the tests of agglutination of the patient's serum.—I am, etc.,

Sherborne, July 28.

J. WHITTINGDALE.

Communal Feeding in Schools

SIR.—The very interesting article by a correspondent on communal feeding in schools (July 26, p. 133) revives an old controversy which is now of national importance. Under the stress of war conditions school feeding has become a general necessity, and all would agree that it should be made an opportunity for teaching the value of good cooking, the wise selection of foods, and a civilized manner of life. But I hope the medical profession will think twice before supporting a demand for communal meals as a normal thing for all children in peacetime. It is a very old tradition that regards the taking of meals together as a strong binding element in family life. It is right and natural that husband and children should look to the mother as the dispenser of food, who satisfies hunger, and provides welcome "treats" on festive occasions. Probably more family discipline and parental authority depend on this than is commonly supposed. In discussing this matter over many years with working-class parents I have often heard this view put forward.

Your correspondent evidently feels that the working-class woman is incapable of providing or even learning to provide healthy and wholesome food for her children. I do not believe this is true to-day, as the good health and physique of the nation show. Working-class women do in fact manage to rear sturdy families under conditions which would defeat many school doctors. Surely our aim should be to help her in this task, and not to take it out of her hands, as would certainly be the ultimate effect of your correspondent's proposals. Man does not live by vitamins alone. I would rather see a nation of children brought up to take their food at humble tables presided over by "dad" and "mum" than a nation reared on balanced meals in "refined" restaurants.—I am, etc.,

July 29.

LETTIE FAIRFIELD.

Thirst at Sea

SIR.—The annotation on thirst at sea (July 26, p. 126) interested me greatly in view of my use of hypertonic salines by the bowel in cholera, although only up to a strength of 1.2%—less than half that of sea-water—and in quantities of 10 to 20 oz. every four hours during collapse. I certainly never saw any harm from it. Although in such a disease as cholera it was not possible to say if it had any effect on the loss of fluid from the bowel, I have no doubt much of the fluid was absorbed. Later, in view of the uncertainty whether any of the salt was absorbed, I only advised the use of an isotonic alkaline saline by the rectum, and a hypertonic one intravenously. I note, however, that Martindale's *Extra Pharmacopoeia* (18th edition, p. 745) advises artificial sea-water containing 2.7% sodium chloride as an enema without any reference being given. Ex-

periments appear to be required to decide if rectal injections of salt water permit of water being absorbed into the system.

I would also suggest an inquiry to determine if the chlorides could be precipitated from sea-water by silver nitrate, or other chemical that will leave a potable fluid after filtering off the precipitated silver salt. If so, the required apparatus might be supplied packed for fixing into ships' boats. Silver salts are expensive, but the precipitates might be saved. Doubtless the Medical Research Council can arrange for an early investigation of these suggestions.—I am, etc.,

London, Aug. 1.

LEONARD ROGERS.

SIR.—Pending a decision, probably unfavourable, on the question of the benefits of the rectal injection of sea-water, would it not be advantageous to determine to what extent fresh water can be diluted with sea water before becoming undrinkable? Since normal saline solution, isotonic with body fluids, contains approximately 1% of sodium chloride, and sea-water about 3%, this suggests that a mixture of two parts of fresh water to one of salt water should be possible. If this were so, then what small supplies of fresh water were available could be eked out considerably. In addition, as is well known, a slightly salted water is, in cases where loss by perspiration is heavy, a better drink than fresh.—I am, etc.,

Chester, July 29.

V. BISKE.

Sulphapyridine in Suppurative Otitis Media

SIR.—I have been much interested in the article by Dr. J. B. Jessiman (March 15, p. 399) on the use of sulphapyridine in suppurative otitis media, and think that the following cases may be of interest in this respect.

An Arab girl aged 12 was admitted to hospital suffering from right lobar pneumonia. She had previously attended for over seven years at irregular intervals with a chronic otitis media, with mastoid involvement, for which a cortical mastoid operation had been performed at the age of about 7. In spite of this an obstinate aural discharge continued, with periodical exacerbations, and no apparent response to local and general treatment. On admission she was extremely ill, with high pyrexia and typical chest signs. There was also purulent aural discharge. She was at once put on to sulphapyridine and local aural treatment; the response was immediate and the child made a rapid and uninterrupted recovery. There was still some discharge from the ear when she left hospital, and she was instructed to attend for treatment. This she failed to do, and was lost sight of for a year, after which she returned to hospital as escort to a friend. She stated that since her discharge from hospital the ear had been dry. On examination a normal passage free from pus and a scarred and sclerosed drum were found. Unfortunately smears of aural discharge were not taken on her admission, all attention being concentrated on her chest condition, but there seems very little doubt that the sulphapyridine given for this was the determining factor in clearing up this previously resistant trouble.

Following this two cases of frank otitis media were treated as follows: (1) Indian boy aged 8 months, twenty-four hours history of fretfulness and pain in the ear. Temperature 101° F. drum of the left ear inflamed and bulging. Sulphapyridine 1/4 tablet given four-hourly and local treatment; twenty-four hours later there was no pain or fever, the child had slept well and the drum, though still slightly injected, was no longer bulging. In three days the child was well. (2) Arab child aged 2 years had had a very septic mouth, with gross dental caries, and necrosis of a large part of the left maxilla, which was removed as a sequestrum at operation. One month later he developed left otitis media, but did not attend hospital until there had been a purulent aural discharge for several days. Local treatment was given with sulphapyridine by the mouth. The condition cleared completely in one week.

I should like, in this connexion, to note that in practically all cases of otitis media in children I have found a positive malaria blood film. I should be interested to know if other practitioners in the Tropics have found this, as in view of the frequency of staphylococcal furunculosis as a sequel to malaria there might be a definite connexion.—I am, etc.,

V. RUTH SHARP.

Pemba, Zanzibar, May 28.

Woman Medical Officer, Chake Chake.

Water-borne Outbreak of Paratyphoid B

SIR,—There has recently occurred in this district a small localized outbreak of paratyphoid B fever due to the consumption of a contaminated water supply.

The evidence collected has proved fairly conclusively that the outbreak—twenty cases out of a "population-at-risk" of twenty-eight—was due to the consumption of water from a pump situated in the old type of court and supplying seven houses only. *Bact. paratyphosum* B has been isolated from the water supply during the course of the investigations by three members of the Emergency Public Health Laboratory Service—namely, Prof. Wilson, Oxford, Dr. Knox, Leicester, Dr. Gell, Northampton; and, furthermore, the organism isolated has been shown to be similar culturally and serologically to the organism isolated from specimens of faeces and urine from the patients concerned. This small outbreak is of particular significance, as there is no evidence in the medical literature of an outbreak of paratyphoid fever being caused through the consumption of a contaminated water supply.

I hope very soon to be able to publish a detailed report of the investigations carried out in this very interesting and unique outbreak.—I am, etc.,

Northampton, Aug. 1.

Protecting Eye Shields

SIR,—May I support Mr. Harrison Butler's plea (July 19, p. 101) for issue of the Cruise vizor? As a practical rifle shot there is no question that there is no difficulty in using the rifle when the vizor is down; in fact it acts as an aperture sight and would help the myope. I cannot understand what there is to experiment on in it. It does protect, it does not obstruct, and it is cheap.—I am, etc.,

London, E.C.4, July 30.

C. WYNN WIRGMAN.

** We understand that as a result of careful and exhaustive tests it was decided not to recommend the issue of the vizor to the Forces.—ED., B.M.J.

Notification of Deficiency Diseases

SIR,—The two Ministries responsible for the maintenance of adequate nutrition of the population under war conditions are at present largely guided by theoretical considerations and lack the means whereby the success or failure of their work can be subjected to any but the roughest of practical tests. The only checks on the adequacy of the national dietary now available are, first, the schools' medical reports; secondly, the incidence of notifiable infectious diseases; and, thirdly, reports of death from starvation collected by way of the coroners' courts. Of these, only the incidence of actual starvation is directly linked to the question of nutrition.

The net is of too wide a mesh to discover a dangerous prevalence of a deficiency disease or subclinical avitaminosis of far wider extent. I believe that owing to the lateness of the spring vegetable season and the scarcity of imported citrus fruits there has been a considerable increase in the incidence of scurvy during last spring and the early summer, and that this could have been avoided had the authorities been aware in good time of the danger.

May I therefore use your columns to make the suggestion that, for the duration of the war at least, deficiency diseases should be made compulsorily notifiable to the Ministry of Health or to the local authority, as are certain infectious diseases? By this means the signals of danger could be received in time enough to prevent a possible outbreak of a deficiency disease by suitable publicity and the distribution of concentrated vitamins.—I am, etc.,

London, N.19, July 27.

HUBERT PEARSON.

The National Loaf

SIR,—If Dr. I. Harris wrote only to the *British Medical Journal* his letter could remain unanswered, it is so barren of real argument. But someone of the same name is both disparaging the national loaf in public meetings and gaining local Press publicity for his views, and that is a very different matter.

Dr. Harris's letter is full of half-truths which are unlikely to deceive the medical reader, but I tremble to think of their effect

on the layman. He says the loaf is to be fortified by calcium alone—he must know that the national wholemeal loaf has five times as much iron, twice as much fat, many times as much vitamins, and the unknown remainder present in natural whole grain but absent in the 73% extractions. He calls the calcium "chalk." Is it not a fact that calcium is added in the form of phosphate? He wants us to have our necessary calcium in milk. Is he unaware that the pre-war consumption of milk was one-fifth of a pint per day per head, and that even then two and a half million more milking cows were necessary to provide the optimum daily pint per head?

Of course we know calcium is ineffective without vitamin D, but is not this supplied with the margarine? A layman could only think that Dr. Harris says the calcium in the national loaf is ineffective. Again, he says there is not a scintilla of evidence that there is a calcium deficiency. Has calcium nothing to do with teeth? Can he produce twelve adults in working-class Liverpool with sound teeth? They have not come to North Wales as evacuees, and if white bread is not responsible for their languid pallor then it is up to Dr. Harris and his colleagues with the advantage of local knowledge to tell us what is.—I am, etc.,

Caernarvon, July 26.

GRIFFITH EVANS.

Suture of Cauda Equina

SIR,—I should be very glad to know of any successful case of suture of the cauda equina. In the official history of the last war it is stated that not a single example was met with, yet most textbooks comment on its feasibility. If, therefore, through the medium of your *Journal* you are able to put me in touch with anyone who has sutured one or more elements of the cauda equina with success I shall be much obliged to you.—I am, etc.,

LAMBERT ROGERS.

c/o Medical Department, Admiralty, S.W.1, July 30.

Sydenham and the Royal College of Physicians

SIR,—Your reviewer of Prof. McDowall's *Biological Introduction to Psychology* (July 26, p. 121) states that Sydenham never became a Fellow of the Royal College of Physicians "probably owing to professional jealousies." This is not correct, as demonstrated by the documents of the College and as stated in the *Life of Thomas Sydenham* by J. F. Payne, a late Harveian librarian of the College and one of our greatest scholar physicians: Sydenham did not become a Fellow of the College because up to an advanced age he had not a doctor's degree and thus, according to the by-laws of the College at that time, was not eligible for the Fellowship. Sydenham obtained a doctor's degree only in 1676, thirteen years before his death, but even then did not apply for admission, as there is no record of any such application in the archives of the College. It is quite possible that at his age he did not feel inclined to present himself at an examination, or possibly the necessities of his practice prevented him from taking an active part in the affairs of the College, which all Fellows at that time were under obligation to do.

There is no question of professional jealousy in all this. On the contrary, according to contemporary documents Sydenham was often praised and given honour by the College.—I am, etc.,

London, W.1, July 28.

Obituary

A. J. CLARK, M.D., F.R.C.P., F.R.S.

Professor of Materia Medica, University of Edinburgh

We announce with deep regret that Prof. A. J. Clark died in Edinburgh on the morning of July 30. He had been pharmacological adviser to the *British Medical Journal* for twenty years, and gave invaluable help at all times to the Editorial Department and to the Journal Committee. He visited London quite recently for a meeting of the Medical Research Council and seemed in his usual health, but he fell ill on July 26 and was operated upon next day.

Alfred Joseph Clark was born at Northover, Glastonbury, on August 19, 1885. He came of Quaker stock, and his father, Francis Joseph

Clark, was the head of a long-established manufacturing firm at Street, Somerset. From Bootham School, York, he went up to King's College, Cambridge, and gained honours in both parts of the Natural Sciences Tripos, taking his B.A. in 1907. Under the influence of the late W. E. Dixon his physiological studies at Cambridge led on to experimental pharmacology, and at St. Bartholomew's Hospital he was clearly marked down for a scientific career. Having

graduated in medicine in 1910, he held the posts of house-surgeon at Addenbrooke's and house-physician at Bart's, and took the M.R.C.P. and D.P.H. He then served in turn as demonstrator of pharmacology at King's College, London, assistant pharmacologist at University College, and lecturer on pharmacology at Guy's Hospital. In 1914 he took his Cambridge M.D., and after the war broke out entered the R.A.M.C. with a temporary commission, and received the Military Cross for gallantry and devotion to duty. When the war was over he sailed to South Africa to take up the chair of pharmacology at Capetown University, but after a short time there he was recalled to University College to fill the professorship for which he had seemed to be destined. After several happy and successful years of teaching and research in London he was appointed in 1926 to the vacant chair of materia medica in the University of Edinburgh.

Prof. Clark was elected F.R.C.P. in 1921, F.R.S. in 1927, and F.R.S. in 1931. He was a member of the Medical Research Council in 1934-8, and again from 1939 to the time of his death. He was also an active member of the Physiological Society, and served on various committees and subcommittees concerned with the actions and uses of drugs and other therapeutic substances. Besides many papers and addresses published in these columns and elsewhere he wrote four books: *Applied Pharmacology*, which was first published in 1923 and reached a seventh edition last year; *Comparative Physiology of the Heart* (1927); *Mode of Action of Drugs on Cells* (1923); and *General Pharmacology* (1938). He liked wandering down bypaths of medicine, and made a special study of the history of anaesthetics and the long tale of quackery through the ages.

The British Medical Association awarded him a research Fellowship in 1911 and 1912, and scientific grants in 1914 and 1919. He was vice-president of the Section of Thera-

peutics and Pharmacology at the Edinburgh Meeting of the Association in 1927 and at the Centenary Meeting in 1932, and was president of the Section of Pharmacology, Therapeutics, and Anaesthetics at Plymouth in 1938. He often visited Tavistock Square, and from 1936 onwards took part in the conferences between representatives of the Science Committee of the B.M.A. and the Pharmaceutical Society.

Sir HENRY DALE, P.R.S., writes:

British pharmacology suffers a new and heavy bereavement in the death of A. J. Clark at the early age of 56 years. The news comes as a shock to a wide circle of friends, mainly workers in the medical sciences, who knew the stimulating quality of his mind and his fine, staunch character. The natural inclination of Clark's interest appeared to be to the study of physiological reactions of a fundamental and generalized type. To this study pharmacology could make its special contribution in showing how drugs modify such reactions. He naturally chose the simplest available physiological schemes for these studies, making use largely of tissues which would survive and remain active in prolonged isolation, such as the frog's heart. To understand the action of drugs on the latter he needed and sought more exact knowledge of its contractile metabolism, the source of its energy, and the conditions determining its normal rhythm. Work on the heart gave scope for another of Clark's interests—that of a naturalist in the varying behaviour and dimensions of such an organ over a wide range of species. He recorded these explorations in a book on the *Comparative Physiology of the Heart*, in a Cambridge series. In this can be found examples of Clark's humorous delight in exhibiting the results of odd calculations and quantitative comparisons. One gets the impression that with a slight change of circumstances or opportunity Clark might easily have found his field of research in experimental zoology. His attention, however, never wandered far from his principal aim—of interpreting the actions of drugs in more fundamental terms. His speculations and researches in this field over many years were embodied in the book on *The Mode of Action of Drugs on Cells*, which brought him wide reputation in many countries, and through which his work is likely to have its most permanent effect on the progress of scientific thought and experiment.

There was, however, another and much more practical side to Clark's interest in pharmacology which must have made him a specially stimulating teacher. This is shown in his *Applied Pharmacology*, in several editions of which, from 1923 onwards, he endeavoured, in his own words, "to bridge the gap between pharmacology and therapeutics," "therapeutics" meaning the methods in actual use or in near prospect at the dates of the successive editions. It included not merely the use of old-fashioned drugs or of drugs in the ordinary sense, but the rapidly developing use of hormones, vitamins, and even radiations. This book was a really remarkable achievement, and showed the range and versatility of one whose own researches had dealt mainly with fundamental and academic problems. The section on "Systems of Medicine" in the introduction to the later editions illustrates Clark's effective use of arithmetic for the purposes of a freakish humour. Hahnemann's recommended dilution of a drug for homeopathic medication, he tells us, "works out at a content of 1 molecule of drug in a sphere with a circumference equal to the orbit of Neptune." Clark found another opportunity for forceful play with this weapon of quantitative humour in his popular tract on *Patent Medicines*, in the "Fact" series. It is sad indeed to think that he will not be there to see the effect of legislation now before Parliament, of a kind for which his brilliant and devastating little book made such an effective plea.

In all these and in many other directions we shall sadly miss one of the brightest and most enterprising spirits from British pharmacology, and a gallant comrade from the ranks of medical research workers.

Sir EDWARD MELLANBY, F.R.S., secretary of the Medical Research Council, writes:

The sudden and unexpected death of Prof. A. J. Clark at the height of his powers is a loss to medical science which can hardly be exaggerated. I wish here to write a few words of appreciation of his work for the Medical Research Council.

He first became a member of the Council in 1934, and his period of office ended in 1938. After an interval of only one year he had the unusual experience of being re-elected to membership, a position he held at the time of his death. Thus Clark belonged to a small group of men, including F. G. Hopkins, C. S. Sherrington, T. R. Elliott, and E. D. Adrian, who have served for more than one period of four years as members of the Medical Research Council. This is just one measure of the Council's appreciation of his wide knowledge of medical science, his wisdom, his reasonableness, and his willingness and ability to help in this important public work.

By his education and natural ability Clark was exceptionally fitted to play an important part in the organization and initiation of medical research by the State. He belonged to the diminishing group of the Cambridge physiology school who were trained to study and appreciate the whole field of experimental medical science. While not necessarily specialists in any one branch, these men learned the fundamentals of experimental physiology, pharmacology, and pathology, and knew when to seek higher authority and call upon the expert for assistance in any particular direction. This did not prevent many of them from becoming leaders in particular lines of study, but never at the expense of their wider outlook. Clark's later experience at St. Bartholomew's Hospital as a medical student and house-physician rounded off his university training and served to extend his knowledge and interest to the science of disease. He succeeded in maintaining his scientific outlook on all biological phenomena, whether in the laboratory or at the bedside. It would indeed have been difficult to find anybody with wider knowledge and greater interest in all branches of medical science than Clark. In his own research his natural instincts often led him to study the more abstruse and fundamental points in biological science, especially the action of chemical agents on living cells, and yet few men have played a greater part in bringing knowledge gained in the laboratory to the practical use of medicine. It was this dual outlook—his interest in the fundamental academic science of biology and his intense appreciation of the need to interweave the work of the laboratory and the ward—which placed Clark in a unique position for helping organized medical research.

An editorial friend writes:

"A. J." was a kind, sincere, and truly modest man, devoted to the science of medicine, and ever anxious to put the laboratory into the service of therapeutics. He took a broad view of pharmacology and its future, and read diligently to keep himself abreast of new work in that rapidly growing field. There was nothing "professorial" in his manner, and indeed at times he seemed a little confused in speech, but he was a good professor, approachable, eager to learn as well as to teach, and radiating love of his subject. Honest himself, through and through, he expected no less of others; towards mere weakness or ignorance he was humorously tolerant. We have lost an understanding friend, a loyal colleague, and a trusted expert adviser.

Medical Notes in Parliament

Medicine and Pharmacy Bill in the Lords

In the House of Lords on July 29, on the second reading of the Pharmacy and Medicines Bill, Viscount PLUMER moved an amendment urging that the House should not proceed at present with a Bill which proposed to grant a trading privilege to pharmaceutical chemists in the sale of medicines and to deprive herbalists of their existing right to sell many herbal medicines.

Lord ADDISON urged that there was no question of haste about the Bill, which had been long wished for, apart from any professional interest, by sensible people.

Lord HORDER agreed with Lord Addison that legislation on the matter was overdue. Two important principles were established by the Bill. First, there was the principle of qualitative and quantitative disclosure. He could not help feeling that it was on the quantitative demand for disclosure that the herbalists had struck. The art and science of healing advanced very slowly, but they did advance. The advance had been made in

the direction of searching out what was the essential ingredient that did good in the various plants and minerals that Nature had provided.

The advances in the treatment of disease in the last decade of this century had been in the direction of exact formulation of essential ingredients.

The second great principle which the Bill established, not for the first time but more extensively, was control over advertisements. The "fear advertisement" was highly dangerous. There was a crying need still for more control over a form of advertisement which was not dealt with in the present Bill. He had been given an assurance that the Government were prepared to inquire into the working of the Bill after a reasonable time had elapsed. That, with the statements of the Minister of Health in the House of Commons, might be regarded as a pledge that the Government would make at least a full survey of the whole position in the near future. The Bill was a step in the right direction and would conduce to the common health.

Lord Plumer withdrew his amendment.

After further debate, the Lord Chancellor said he agreed with Lord HORDER that the Bill went in the direction of reform on two or three matters where reform was very much overdue.

The Bill was read a second time.

Mr. Churchill on Work, Rest, and Diet

During his speech in the House of Commons on the production of war materials, on July 29, Mr. CHURCHILL said that in the three months after Dunkirk our people worked to the utmost of their moral, mental, and physical strength. Men fell exhausted at their lathes, and working men and women did not take their clothes off for a week at a time. Meals, rest, and relaxation all faded from their minds, and they just carried on to the utmost limit of their strength. There were one or two reasons why we could not wholly recapture and maintain indefinitely the intense personal efforts of a year ago. We should win the war largely by staying power. For that purpose there must be reasonable minimum holidays for the masses of the workers, one day in seven of rest as a general rule, and, subject to coping with bottle-necks and with few emergencies which knew no law, a few breaks, and, where possible, one week's holiday a year. Allowances must be made for the very severe change in the diet of the heavy manual worker. It was quite true that no one had gone short of food, and there had been no hunger, but no one could pretend that the diet of the British people, and especially of the heavy workers, had not become far less stimulating and interesting than it was a year ago. Except for the fighting Services we had been driven back to a large extent from the carnivore to the herbivore. That might be quite satisfactory to the dietetic scientists, who would like to make us all live on nuts, but it had produced and was producing a very definite effect on the energetic output of the heavy worker. More meat was wanted in the mines and in the foundries, and more cheese. Great arrangements had been made to send food from America in nourishing, varied, and more interesting quantities. Every effort would be and was being made to supplement this deficiency, and he shared the hope of the Minister of Food and the Minister of Agriculture that our rations in 1942 would be more stimulating and more nourishing than in 1941.

American Doctors for Britain

On July 29, Sir HENRY MORRIS-JONES asked the Minister of Health what progress had been made with the proposal, recently announced by him, for securing the services of 1,000 doctors from the United States of America to help in the medical services of this country. Miss HORSBROUGH replied that the scheme had not yet become fully operative. According to information recently received from the American Red Cross about eighty United States doctors who had applied under the scheme were at present being considered for acceptance, in addition to one who had already arrived and was at work in a civil hospital and four who were on their way to this country.

N.H.I. Statistics

On July 29, Miss HORSBROUGH, replying to Mr. Thorne, stated that on December 31, 1939 (the latest date for which such information could be given), the number of insured persons in

Great Britain was: men and boys, 14,204,000, including 141,000 deposit contributors; women and girls, 7,243,000, including 155,000 deposit contributors. The total sum paid out in benefits in the year ended December 31, 1940, was £34,197,000, the accumulated funds at that date amounted to £146,799,000, and the amount invested by or on behalf of approved societies to £61,224,000. The expenditure in the year ended December 31, 1940, on sickness, disablement, and additional benefits was:

	Men £	Women £	Total £
Sickness benefit ..	8,114,000	4,024,000	12,138,000
Disablement benefit ..	3,781,000	2,029,000	5,810,000
Additional benefits:			
Cash ..	1,479,000	304,000	1,783,000
Non-cash ..	—	—	2,416,000

(Separate figures in weeks were not available)

The fifth valuations of the approved societies would be completed during the coming autumn, and it was expected that a short report by the Government Actuary, incorporating some statistics of the results, would be available early next year.

EPIDEMIOLOGICAL NOTES

Infectious Diseases for the Week

In England and Wales there was a decline in the incidence of the principal notifiable diseases during the week, with the exception of dysentery and enteric fever; the former is over four times and the latter over three times as prevalent as last year. Though a seasonal rise in these diseases may be expected, especially during hot weather, the recent increases would give cause for alarm were it not that the prevailing type is mild—namely, Sonne dysentery and paratyphoid B fever. On the other hand, acute poliomyelitis—another disease of hot dry weather—is exceptionally infrequent. Cerebrospinal fever, in respect of which an exacerbation was recorded last week, is at exactly the same level as last year, and in Scotland at nearly the same level.

Enteric Fever

The Lancaster outbreak, involving Liverpool chiefly, has surpassed that of Birmingham and district in both magnitude and geographical distribution, being widely scattered over the county and in the adjacent county of Chester, chiefly in Birkenhead. No details are as yet available as to the source and mode of spread of the infection. Apart from the counties heavily affected, no area recorded more than 6 cases: Lancaster 146 (Bootle 9, Liverpool 79, Manchester 15, Preston 2, St. Helens 18, Salford 2, Southport 1, Wigan 1, Ashton-under-Lyne M.B. 1, Crosby M.B. 2, Failsworth U.D. 1, Huyton with Roby U.D. 1, Irlam U.D. 1, Morecambe and Heysham M.B. 1, Prescot U.D. 1, Urmston U.D. 1, Widnes M.B. 4, West Lancashire R.D. 4, Whiston R.D. 1, Wigan R.D. 1); Chester 63 (Birkenhead 28, Chester 1, Stockport 1, Wallasey 14, Bebington M.B. 16, Dukinfield M.B. 1, Ellesmere Port U.D. 1, Wirral U.D. 1); Stafford 21 (Stoke-on-Trent 11, Wolverhampton 1, Newcastle-under-Lyne M.B. 1, Stafford M.B. 6, Stone R.D. 2). In Scotland, of the 24 cases notified 5 (3 in Glasgow and 2 in West Lothian) were of typhoid fever; the remaining cases were recorded in Glasgow 7, Dundee 6, the counties of Ayr and Lanark 2 each, Dumfries County 1, Moray and Nairn County 1.

Dysentery

Only fourteen administrative areas were affected by dysentery, compared with twenty-nine with enteric fever. In none was incidence heavy or widespread, and only in three were there more than 6 cases—namely, Essex 21, all in Brentwood U.D.; Lancaster 13 (Blackburn C.B. 1, R.D. 4, Warrington R.D. 7, Whiston R.D. 1); West Riding of Yorkshire 13 (Bradford 5, Wakefield 1, Aireborough U.D. 7). In Scotland, of the 35 cases notified 11 were in Dundee, 6 in Edinburgh, 5 in Glasgow, 3 each in Coatbridge and Paisley, and the remaining 6 in four counties and one burgh.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics for the British Isles during the week ended July 12.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1941					1940 (Corresponding Week)

* Includes primary form in figures for England and Wales, London (administrative county), and Northern Ireland.

† Owing to evacuation schemes and other movements of population birth and death rates for Northern Ireland are no longer available.

Universities and Colleges

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At the quarterly meeting of the Council, held in the College House on July 26, with the President, Prof. W. Fletcher Shaw, in the chair, the following officers were elected to take office in October.

President: Prof. W. Fletcher Shaw. *Vice-Presidents:* Mr. Eardley Holland and Prof. C. G. Lowry. *Honorary Treasurer:* Mr. J. P. Hedley. *Honorary Secretary:* Mr. G. F. Gibberd. *Honorary Librarian:* Wing-Commander F. W. Roques, R.A.F.V.R. *Honorary Curator of Museum:* Mr. Aleck W. Bourne.

The following were admitted: *To the Fellowship:* N. L. Edwards, W. A. Taylor, R. Watson. *To the Membership:* J. Joseph.

The following candidates were elected to the Membership: G. Boyd, D. S. Foster, E. Gledhill, Constance E. Peaker, Kathleen M. Robinson, Katharine C. Rogers, R. X. Sands, Violet E. A. Sykes, G. Wynn-Williams.

Medical News

The Annual Congress of the Ophthalmological Society of the United Kingdom will be held, circumstances permitting, in Cambridge on September 4 and 5, 1941. The subject for discussion will be "Ocular Injuries resulting from the War," and the openers will be Dr. O. M. Duthie (Manchester) and Dr. S. Zuckerman (Oxford). It is possible that all male members can be accommodated in college. It is desired that all who hope to attend will notify at an early date the honorary secretary, Mr. Frank W. Law, F.R.C.S., 36, Devonshire Place, London, W.1.

Medical practitioners are informed that the Food Rationing (Special Diets) Advisory Committee of the Medical Research Council has recommended that persons suffering from nephrosis or the nephrotic type of glomerulo-nephritis should be granted three extra meat rations a week. Doctors may therefore complete certificates on behalf of their patients suffering from these diseases for submission by the patient to the local Food Office.

The Board of Education has asked local education authorities to review their school medical services, with a view to releasing doctors and dentists for the Services. Routine medical inspection of school entrants must be maintained, but many other surveys, it is suggested, might be undertaken by school nurses, while doctors of foreign nationality who have been registered in this country might be employed.

Four years ago the National University of Mexico founded its social service system under which every medical graduate is required to practise for five months as a health officer in some part of the country where there is no such representative. He sends in a weekly report of contagious diseases cases seen, and a monthly report which includes information on sanitary questions such as water supply and drainage. Since 1935 more than 100 graduates have taken part in this social service programme.

Lieut.-Colonel Sir Henry Gidney, I.M.S. (ret.) has been appointed a member from British India on the new Indian National Defence Council.

Dr. Gerhard Domagk, professor of morbid anatomy at Münster, who first introduced prontosil, has been made an honorary member of the Spanish Academy of Dermatology and Syphilology.

The May issue of *Annals of Surgery* is a special number devoted to "Surgical Preparedness Symposia."

The Canadian Red Cross Society will send 300,000 lb. of Canada's jam to Britain this year.

A new wing in the Salvador Hospital at Santiago, Chile, has been dedicated to the memory of Harvey Cushing.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS of their articles must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be addressed to the Secretary.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent*, London; SECRETARY, *Medisecra Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Income Tax

Employment by Self and Wife: Housekeeper

"GAMMA" is employed as non-resident medical superintendent of a municipal hospital, and his wife has been appointed whole time to the staff of the M.O.H. for the duration of the war. Consequently it has been necessary to employ a housekeeper. Can an allowance be claimed for this expense?

** No. The point was decided in the case of *Brewers v. Harding* on very similar facts.

LETTERS, NOTES, ETC.

An M.O.H. and the R.M.B.F.

Dr. LEWIS G. GLOVER, honorary treasurer of the Royal Medical Benevolent Fund, writes: I desire to acknowledge through your columns the receipt of the following letter, signed "Medical Officer of Health," in recognition and gratitude to you as well as to the donor. "I recently noticed in the medical press the suggestion that doctors who have received kindness in the form of medical attention to themselves and their families from other doctors should recognize the fact by making a grant to the Royal Medical Benevolent Fund which, to a certain extent, expressed their gratitude. The difficulty of making some return is increased when the recipient doctor is a medical officer of health. I think the suggestion made is therefore helpful, and I propose to follow it in the future and now enclose a 'token' subscription representing in a small way my appreciation for the kindness displayed to myself and family by medical practitioners." As the "token" was a very generous cheque I desire to express my grateful thanks both to the donor and also to you. It is possible that others who may read this letter may be encouraged to follow the example which I am glad to record is being taken up.

Ether Convulsions

Dr. C. LEONARD TRAYLEN (London, N.W.10) writes: May I point out that in my letter (July 12, p. 67) no stress is laid on the fact that no hot ether was used. Dr. Charles Wells was inclined to suggest that this was a cause.

Problems of the Circulation

Dr. G. ARBOUR STEPHENS (Swansea) writes: Prof. McDowall is to be thanked for his two lectures on the problems of the circulation (July 12 and 19), in which he pleads for a closer relation between physicians and physiologists, and deprecates the restriction of diagnosis to restricting formulae. It is interesting in this connexion to note that he, as a physiologist, believes that a muscle when it contracts produces no sound, while teachers of medicine contradict him when they say the sounds of the heart are due in part to the contraction of the heart muscle. Prof. McDowall speaks of "high pressure," but does not define it. In 1932 I pointed out that the height varies according to the width of the armlet, and for that reason emphasized the need for a standard width. He makes no reference to what I hold is of great importance—namely, the restriction of blood flow into the vasa vasorum when the pressure on the blood in the arteries is increased. I hold that the ratio of the systolic pressure to this pressure in the arteries, against which the heart stroke has to pump the blood, is of the greatest importance in connexion with cardiological problems.

ANAEROBIC CELLULITIS AND GAS GANGRENE

BY

GEORGE QVIST, F.R.C.S.

Surgical Registrar at the Royal Free Hospital

Infective gangrene in wounds is a subject of no little importance at present, and while our knowledge is yet far from adequate, enough facts have been established to render unnecessary some of the confusion which still exists regarding its diagnosis and treatment. Differences of opinion are greatest on the question of treatment, and there are wide divergencies in the results obtained from any individual method. These discrepancies are due in part to lack of differentiation between gas infection of the cellular connective tissues and true gas gangrene of muscle. A faulty diagnosis of gas gangrene is often made because attention is focused on the demonstration of gas or of gas-gangrene organisms in a wound instead of on the tissues in which the gas is produced, so that cures of gas gangrene are claimed as due to some particular treatment when in fact the condition was no more than a subcutaneous gas infection without involvement of muscle.

There are two stages in the diagnosis of a gas-infected wound: the first is the demonstration of gas, and the second the identification of the tissue involved. The demonstration of gas or of gas-gangrene organisms is easy and may be made by clinical, radiological, or bacteriological means; but the distinction between gas infection of the connective tissues and gas gangrene of muscle is more difficult and far more important, and can be made only on clinical grounds, radiology and bacteriology playing no part.

Three groups of cases occur; in these the organisms of infective gangrene may be found in a wound (1) as harmless saprophytes in ulcers, with no pathogenicity; (2) as pathogenic organisms producing an infection of the cellular connective tissues—gas infection of a wound or anaerobic cellulitis; or (3) as invaders of muscle—true gas gangrene.

1. Saprophytic Anaerobes

Numerous observers have described the saprophytic form of gas-gangrene organisms. Thus Fleming in 1915 found *Cl. welchii* in 127 out of 210 war wounds of varying ages; Manson (1932) found gas-producing anaerobes in 11 out of 32 chronic ulcers of the limbs; and Roberts, Johnson, and Bruckner (1933) found clostridia in 21.7% cases of unprepared abdominal skin, on 8.5% of surgical knife blades, and from the peritoneum in as many as 14.2% cases operated on for non-inflammatory conditions. Saprophytes of this type are capable of producing toxins: Muriel Robertson (1941) found highly toxic types of *Cl. welchii* in recent wounds, their presence in which had caused no symptoms. The bacteriological demonstration of gas-gangrene organisms in a wound has therefore little surgical significance.

2. Anaerobic Cellulitis

Gas infection of a wound without gangrene of muscle is probably the commonest clinical type of active infection

by the gas-producing anaerobes. In this condition gas is produced in the wound, which may be demonstrated both clinically and radiologically; but there is no infection of muscle, and the patient may well recover without any active treatment. It is certain that many of these cases have been described as gas gangrene and reported as having been cured by different methods of treatment.

The site of the infection is the cellular connective tissues, and therefore there is no reason why the condition should not be recognized by the term "anaerobic cellulitis," comparable to other forms of cellulitis such as the streptococcal type. Following compound injury, and quite apart from muscle damage, conditions in the subcutaneous tissues may favour the growth of anaerobic organisms, with gas production from the proteins and carbohydrates in these tissues and from associated haematoma. This anaerobic cellulitis may spread in the fascial planes for some distance, but in the absence of a suitable pabulum of damaged muscle the infection may remain superficial or completely resolve when the supply of connective-tissue media is exhausted or when anaerobic conditions are terminated by suitable surgical incisions. An important feature in such cases is that the musty odour typical of gas gangrene is not present; this is probably to be correlated with the absence of muscle necrosis. With this local growth of anaerobes toxins are no doubt produced, and the patient suffers from a toxæmia of varying severity, depending on the extent of the damaged tissues and the nature and virulence of the organisms.

This condition is the one referred to usually as "local gas gangrene," but in the absence of muscle infection it would be preferable to distinguish it as "anaerobic cellulitis," particularly because its prognosis and treatment are so different from those of gas gangrene. Obviously the local treatment need never be drastic; if one can be certain that the condition is no more than a cellulitis, there is no necessity for radical surgery. Adequate treatment consists in removing skin stitches and opening up the wound or, in a more extensive case, making incisions under an anaesthetic. In addition, serotherapy and chemotherapy must be instituted, partly to mitigate toxæmia and also because they may help to arrest spread of the infection to muscle of impaired vitality, should any be present in the wound.

The following are three cases of anaerobic cellulitis:

Case 1.—Male aged 30. Road accident, 4/11/38. Multiple abrasions and contusions of lower limbs, with a puncture wound just above the left knee. Given 1,000 units of A.T.S. and 4,000 units of polyvalent anti-gas-gangrene serum. Operation two hours later showed only a large subcutaneous haematoma of the left thigh, and the wound was excised and sutured. On the fourth day there were signs of a gas infection, with crepitus and gas bubbles in the wound. The general condition was fairly

good. T. 101°, P. 108. Under general anaesthesia the wound was opened up and the infection was found to involve only the subcutaneous tissues. It was left open, with hydrogen peroxide dressings, and the infection soon resolved, the temperature becoming normal in three days. Culture of the wound exudate showed *Cl. welchii*.

Case 2.—Female aged 19. Road accident, 28/9/38. Multiple abrasions and lacerations of lower limbs and right hand. Given 1,000 units A.T.S.; wounds excised and sutured. The laceration of the right foot involved the incomplete avulsion of a large piece of skin of the dorsum with considerable soiling by road dirt. Next day the patient was ill. T. 101°, P. 134. Given 10,000 units of anti-gas-gangrene serum and 2 grammes of sulphamylamide t.i.d. A few stitches were removed from the wound of the right foot, when a little odourless brownish fluid escaped. The pulse remained 120-130 until the next day, when there were crepitus and gas bubbles in the wound. A further 20,000 units of anti-gas-gangrene serum was given. Culture of the wound exudate showed *Cl. welchii*. The general condition improved on the third day; there was no spread of the gas infection, and the wound suppurated and eventually developed a clean granulating surface.

Case 3.—Male aged 45. Air-raid casualty, 9/11/40. Compound fractures of left femur and left hand and perforating wound of left leg. Given 3,000 units A.T.S. Excision of wounds and packing with vaselined gauze four hours after injury. The wound of the left leg consisted of a penetrating track through the gastrocnemius; the limb was immobilized with skeletal traction. Immediately after operation he received 10,000 units anti-gas-gangrene serum and 2 grammes of sulphapyridine intramuscularly, the latter being continued as 1 gramme four-hourly. The following day, twenty-four hours after injury, the general condition was fair; T. 99°, P. 120. There was discoloration of the skin of the antero-lateral surface of the left leg just below the wound, with crepitus in this area, and a radiograph showed the presence of gas. There was a mild odour of stale blood in the wound, but no suggestion of the mouse-like smell of gas gangrene. Culture of the exudate showed *Cl. welchii*. Anti-gas-gangrene serum was given, a total of 150,000 units being injected during the next twenty-four hours in doses of 10,000 and 20,000 units at two-hourly intervals into the left thigh and upper end of the leg above the wound. Crepitus disappeared after twenty-four hours, and the wounds suppurated. The Hb on the fifth day was 50%, with 15,700 white cells per c.mm. The fracture united well and the wounds healed within fourteen weeks.

3. Gas Gangrene

The term "gas gangrene" should be reserved for the type of case in which there is gas production with necrosis of muscle. Its prognosis and treatment are different from those in anaerobic cellulitis, and failure to make this distinction is almost certainly the principal reason for the inconsistency of the results reported from various individual methods of treatment, particularly by x rays. While in every wound with anaerobic gas infection we should suspect gas gangrene and watch closely for it, it is unjustifiable to label every case as such unless or until it is established that there is muscle necrosis. It is of interest to note that the earlier clinical descriptions made this distinction clear, whereas more recent writers seem to neglect the point. Thus Fraser (1919), in discussing the types of anaerobic wound infection, clearly recognized anaerobic gas infection of the wound and gas gangrene of muscle, and Keen (1918) also regarded the distinction as of importance. More recently Hosford (1940) and Jocelyn Swan (1940) have called attention to it, and Tudor Edwards (1940) similarly emphasizes the difference between the two conditions.

Diagnosis of gas gangrene resolves itself therefore into the collation of evidence of necrosis of muscle, and the value of any signs and symptoms must be considered with reference to their use in this respect. These are: (a) general signs; (b) local signs; (c) clinical symptoms and signs; (d) inspection of muscle.

GENERAL SIGNS

The toxæmia of an established case of gas gangrene is of course severe, and a gas-infected wound in an extremely ill patient is almost certainly the site of infective necrosis of muscle. But in anaerobic cellulitis without muscle damage there is also a toxæmia, difficult to distinguish from early gas gangrene: it is after all merely a question of degree of toxæmia, since the organisms and toxins may be identical. All three cases of anaerobic cellulitis described above showed toxæmia, particularly Case 2, with raised temperature and pulse rate. Furthermore, it is often difficult to make an exact clinical estimate of the severity of a toxæmia. Again, the signs suggestive of gas-gangrene toxæmia, particularly the raised pulse rate, may be due to shock following the injury, primary haemorrhage, operation, or associated injuries. There are no constitutional symptoms or signs which are absolutely diagnostic of muscle necrosis.

LOCAL SIGNS

(a) *Bacteriology*.—The finding of anaerobic organisms does not give any information about the involvement of muscle.

(b) *Radiology*.—The demonstration of gas in a radiograph does not prove that this is being produced by disorganization of muscle. In Case 3 the radiograph showed gas, but there was never any clinical evidence of gas gangrene, and the gas was no doubt in the connective tissues. The use of radiography has been well summed up by Ogilvie (1940): "X-rays will disclose gas in the tissue planes, but the method is not particularly helpful, since the discovery of gas and the diagnosis of gas gangrene are two different things. The use of x-rays in diagnosis refers to gas infection rather than gas gangrene. If a case is not clinically one of gas gangrene the discovery of gas in a film will not make it so; if it is, photography is a waste of time."

CLINICAL SYMPTOMS AND SIGNS

Pain.—The complaint of pain in the presence of a gas-infected wound is suggestive of muscle involvement, but it is not always a symptom, and only one of the four cases described below had pain of any severity.

Odour.—This is one of the most important clinical signs, because it is probably due directly to the breaking down of muscle tissue as distinct from the connective tissues. The odour of gas gangrene is distinct; it is a musty or mouse-like smell quite different from the odour of stale blood which occurs in a discharging wound a few days old, such as is associated with anaerobic cellulitis. Unfortunately the actual chemistry of the odour is unknown; it would be valuable to have biochemical proof that the gas is formed from the protein or carbohydrates of muscle tissue. But clinical experience very strongly suggests that this particular gas emanates from the action of anaerobes on muscle and on no other tissue. If it is agreed that the breakdown of muscle alone gives rise to this particular odour, then this is the only sign (apart from direct inspection of the muscle) that is pathognomonic of gas gangrene as compared with anaerobic cellulitis. It is certainly a fact that, in spite of numerous other suggestive signs, the experienced surgeon when asked to see a doubtful case will base his diagnosis almost solely on the local clinical inspection of the wound, with particular reference to the odour. Thus Ashurst (1929) says that in the Second Battle of the Marne it became his habit "to wander around the corridors and smell the patients. Those that smelled like mice were operated on right away because they had gas gangrene. The rest of them could wait awhile."

In the present lack of knowledge of the exact nature and cause of the odour, the most that can be said is that it is probably the result of the action of one or more individual anaerobes on muscle tissue and that it is present in most cases of gas gangrene. Since infective gangrene may be due to a variety of organisms, it is not to be expected that all cases will have the characteristic odour, or even that all cases will have gas. Cases of infective gangrene in wounds without gas production have been described: Ghormley (1935) described one such case in which *Cl. septicum* was identified. This type of case is unusual: undoubtedly in the vast majority of cases of infective gangrene of muscle there is gas production with the characteristic odour.

INSPECTION OF MUSCLE

This of course provides the most valuable evidence, but involves operation. Diagnosis is always confirmed thus and the extent of the lesion is determined. The gross features are well recognized and will not be described. The criteria of viability of muscle have been well summarized by Ghormley (1935) as: "If the muscle is red it may be viable; if it contracts when pinched it is usually viable; if it bleeds freely it is probably viable."

The diagnosis of gas gangrene is therefore essentially a clinical one, and depends mostly on the local signs, of which the most important is the odour. It is probably the experience of many that more cases are diagnosed in the early stages by the inspection of a wound as a deliberate routine rather than as the result of a suggestive temperature chart. It follows that a four- or six-hourly examination of the wound should be the practice in the immediate post-operative period in cases in which gas gangrene is a likely complication.

Clinical Types of Gas Gangrene

The commonly recognized types are: (1) local, (2) single muscle, (3) group of muscles, (4) segment of a limb, (5) fulminating.

It is suggested that this classification does not emphasize the important distinction between the first type, "local gas gangrene," and all the others. "Local gas gangrene" is really a cellulitis, not involving muscle, and it should be separate from the others, which differ among themselves only in degree: (1) Anaerobic cellulitis (so-called "local gas gangrene"). (2) Gas gangrene: (i) single muscle, (ii) group of muscles, (iii) segment of a limb, (iv) fulminating. This is not an academic distinction; its recognition would help to avoid confusion in diagnosis, in treatment, and, perhaps as important as anything, in the evaluation of methods of treatment.

Predisposing Factors in Gas Gangrene

In a wound contaminated with suitable anaerobes there must be factors which determine the infection of muscle as distinct from the connective tissues. These factors may be: (1) Variations in virulence of the organisms. (2) Suitable conditions for growth of organisms: (a) anaerobic conditions; (b) damaged muscle.

Variations in Virulence.—It is a well-known bacteriological fact that organisms vary in toxicity and invasiveness. It may be important in gangrene, but in any case it is a subject about which very little can be done in a practical way.

Suitable Conditions.—According to Eliason, Erb, and Gilbert (1937), "the important single factor in the production of gas gangrene is not contamination with the organism

per se but rather a suitable soil in which it can grow." The essential medium is well recognized to be damaged muscle, and it may be effective in any particular case in one or more of three ways: (i) direct trauma to muscle; (ii) impaired blood supply; (iii) delayed excision. It is not necessary to go further into these well-established points, of which the three cases described below are illustrative.*

Case 4.—Male aged 42. A.R.C., 8/10/40. Antero-posterior perforating wound of upper third of left thigh and a small laceration 3 inches long on the lateral side of left calf. Operation seven and a half hours after injury showed a large haematoma due to a puncture wound of the upper third of the femoral artery, which was ligated. The leg wound showed bruising of a few fibres of the gastrocnemius. The wounds were excised and packed with flavine gauze, and sulphapyridine therapy was instituted. Post-operatively there was no pain in the leg, but inspection thirty hours after injury showed discoloration around the leg wound, with crepitus and the typical musty odour of gas gangrene. Amputation through the lower third of the thigh was performed, and subsequent progress was good. The two important predisposing factors in this case no doubt were the damaged femoral artery and delayed operation, the diminution of blood supply being sufficient to determine the rapid onset of gas gangrene in the presence of infection even in such a trivial muscle injury.

Case 5.—Male aged 26. A.R.C., 8/10/40. Multiple small lacerations of face, chest, right arm and forearm, and both legs. Operation eight hours after injury. There was a laceration 4 inches long on the back of the left leg, with some muscle damage, which was excised and sutured, with drainage. The numerous other wounds were excised, exploration of the right arm showing a complete division of the brachial artery. Post-operative sulphapyridine and anti-gas-gangrene serum therapy was instituted. Gas gangrene developed in the left leg fifty-four hours after injury, by which time he had been given 10 grammes of sulphapyridine and 80,000 units of anti-gas-gangrene serum. Amputation through the lower third of the left thigh was performed, and the subsequent progress was satisfactory. The right forearm developed some muscle necrosis and dry gangrene of the tips of the second, third, and fourth digits. The wound in the leg giving rise to gas gangrene was small, and the deciding factor in the case must have been its delayed local treatment.

Case 6.—Male aged 59. Railway accident, 18/4/40. Compound dislocation of right ankle-joint, with severely crushed foot, and compound fractures of upper thirds of left tibia and fibula, with considerable laceration of the calf muscles. General condition poor throughout. After two hours the left leg, which was attached only by nerves and a few muscle fibres, was removed in the patient's bed under local novocain and the stump packed with flavine gauze. Operation five hours later, the amputation stump being excised and the right foot amputated through the ankle-joint, the wounds being packed with flavine gauze; 3,000 units of anti-gas-gangrene serum given. Gas gangrene developed in the left thigh seventeen hours after injury, and the patient rapidly became delirious, dying ten hours later. The wound exudate contained *Cl. welchii* and other organisms in great numbers.

Prophylaxis of Gas Gangrene

Excision of Wound.—It is well recognized that the one almost certain way of avoiding gas gangrene is by immediate and complete excision of damaged tissue, especially muscle. The importance of the time factor should be emphasized. Actual practice, of course, may fall short of these desiderata owing to such things as the nature or severity of the injury or to the delay incurred in resuscitation from shock, in transport, or in arranging operation; so that it is important to promote other means of prevention, it being always understood that they are supplementary

* Cases 4, 5, and 7 have already been described in the *British Medical Journal* (1941, 1, 273).

to, and not substitutes for, excision. In advocating the use of serum, Bates (1937) says: "Prophylactic serum without intelligent surgery cannot be expected to prevent the development of gas gangrene."

Sulphonamides.—Experimental evidence strongly supports the use of sulphonamides in prophylaxis. Thus Stephenson and Ross (1940) found that sulphanilamide and sulphapyridine protected mice from lethal doses of *Cl. welchii* and *Cl. septique*, sulphapyridine being more potent, although they were of no use against *Cl. oedematiens*. The best results were obtained from the combined use of sulphapyridine and serum therapy. Hawking (1941) has similarly obtained good results in guinea-pigs, the most effective drug being sulphathiazole, and the best route the local application. His results also showed the importance of immediate treatment, a delay of two hours considerably reducing its value and six hours rendering it useless. There is not yet enough material available to estimate the prophylactic value of the sulphonamides in gas gangrene clinically, but it is to be hoped that the results may support the experimental evidence. It is probably best to give sulphonamides both internally and locally in the wound, and it may even be wise to institute such treatment from the time of admission of the patient, before operation. Considering the rapid onset of gas gangrene, which under suitable conditions may well be from the moment of injury, it is likely that immediate local administration is the most important of all methods. Gordon Watson (personal communication) recommends the application of as much as 40 grammes of sulphanilamide to the wound. In the following case gas gangrene developed in an amputation stump in spite of the administration of a standard prophylactic dose of sulphapyridine given by intramuscular injection (8 grammes): no local application of the drug had been made.

Case 7.—Female aged 16. A.R.C., 8/10/40. Compound fracture of upper thirds of left tibia and fibula. Amputation through the lower third of the thigh, performed two and a half hours after injury, with closure and drainage. Post-operative sulphapyridine therapy instituted. Gas gangrene developed in the stump thirty-six hours after injury, the patient having had 8 grammes of sulphapyridine but no anti-gas-gangrene serum. The wound was opened up and irrigated with hydrogen peroxide, and 40,000 units of anti-gas-gangrene serum were given, but the patient died in seven hours.

Antisera.—Opinion is divided about the use of anti-toxic and anti-bacterial sera. Experimentally, good results have been obtained by the combined use of serum and sulphonamides (Stephenson and Ross, 1940). Henderson and Gorer (1940) found that in mice the best effects were obtained by the combined action of sulphapyridine and antitoxin, or of sulphapyridine and anti-bacterial serum, against infections by *Cl. septique* and *Cl. welchii*. It seems that the use of serum in addition to the sulphonamides is advisable. It is probably best given both intramuscularly around the wound and intravenously. Case 3, which developed a *Cl. welchii* infection that remained localized as a cellulitis, was treated by repeated local intramuscular injections of serum.

Adequate prophylaxis should therefore probably comprise: complete and immediate excision of the wound; administration of sulphonamides, particularly local application; injection of antisera, especially intramuscularly around the wound.

Treatment of Gas Gangrene

Successful results in the treatment of gas gangrene have been recorded with methods varying from the most conservative, such as x-ray therapy, to the most drastic, such as

amputation, and the unbiased critic must find it difficult to believe that one disease could call for such widely differing treatments. Thus while amputation is carried out as a life-saving procedure by some, others condemn this measure under any circumstances, as, for example, Kelly and Dowell (1936), who, in recommending x-ray treatment, say: "Since there is so much shock connected with amputation, and, furthermore, since the diseased area is not all eliminated by some of these amputations, it again seems worth while to omit amputations as an obsolete therapeutic procedure for gas bacillus infection."

Obviously, either many unnecessary operations are being performed or conservative treatment is being applied to a different class of case. Almost certainly the latter is a true explanation of these apparent discrepancies in the results of treatment, and results of numerous cases of anaerobic cellulitis have probably been reported as cures of gas gangrene by conservative means. It is essential to be certain that the case is not simply one of cellulitis before being satisfied that a particular treatment has successfully overcome gas gangrene.

The various forms of treatment are local excision and amputation, sulphonamides, antisera, and x rays.

Excision.—There is no doubt that if infective necrosis of muscle is present the only sure way of dealing with it is by adequate excision. If it is localized to one muscle or muscle group, these may be removed; if it is more extensive, involving a segment or more of a limb, amputation is called for.

Sulphonamides.—As in prophylaxis, there is every reason to use these drugs as a local application as well as by general administration. Again, their use does not dispense with adequate surgical excision. Bohlman (1937) reported three cases of gas gangrene which recovered after sulphanilamide therapy, and Jocelyn Swan (1940) recorded two successful cases following sulphonamide treatment in addition to surgery.

Antisera.—Bates (1937) reported 16 cases treated without serum in which the mortality was 50%, and 16 cases in which serum was used, with a mortality of 18%. Larson and Pulford (1930) reported 6 successful results in 7 cases treated with anti-gas-gangrene serum, the injections being made intramuscularly locally around the wound as well as intravenously. It is probably advisable to use antisera in this way in all cases.

X Rays.—Cases of success from x-ray treatment have been reported—e.g., by Kelly and Dowell in 1936. While it is impossible to be certain, it is very probable that the type of case which recovers with x-ray treatment is not true gas gangrene but anaerobic cellulitis. If, for example, Cases 1, 2, and 3 above were to be loosely called "local gas gangrene" they might be regarded as cures of gas gangrene due to any particular treatment that was given. It is essential in evaluating treatment to be certain of the presence or absence of muscle infection, and not to use the term "gas gangrene" unless muscle necrosis is present.

Summary

It is suggested that more care should be given in distinguishing between gas infections of the cellular connective tissues and true gas gangrene, and that the term "anaerobic cellulitis" should be used to describe the former.

Gas infections of wounds should be classified as: (1) anaerobic cellulitis (so-called "local gas gangrene"); (2) gas gangrene—(i) single muscle, (ii) group of muscles, (iii) segment of a limb, (iv) fulminating.

The importance of this distinction is in diagnosis, treatment, and evaluation of treatment. It is suggested that inclusion of all

varieties of gas infection of wounds as gas gangrene has been responsible for considerable diversity of opinion on the value of different methods of treatment.

The differentiation is essentially a clinical one, and the importance of odour as a sign of gas gangrene is stressed.

The histories are given of three cases of anaerobic cellulitis and four cases of gas gangrene.

My thanks are due to Mr. Cecil Joll and Mr. Charles Gray for advice, and to the honorary staff of the Royal Free Hospital for permission to publish these cases.

FURTHER OBSERVATIONS ON ANTI-SEPTIC SNUFFS

BY

M. E. DELAFIELD, M.B., B.Ch.

AND

EDITH STRAKER, M.B., B.S.

*Emergency Public Health Laboratory Service, London School
of Hygiene and Tropical Medicine*

In continuation of the work previously described (Delafield *et al.*, 1941) some further observations on the effect of antiseptic snuffs on nasal carriers of staphylococci and other organisms are now presented. Seventeen of the subjects who provided the material for the earlier report have been further examined for twenty weeks—from early January to the middle of May. Nasal swabs, one from each nostril, were taken as before on three consecutive days each week and the technique of examination was in every respect identical with that previously described.

The Antiseptic Snuffs Tested

The snuffs which were the chief subjects of study had the following composition:

Sulphathiazole Snuffs:

- (a) 10 parts by weight of sulphathiazole
90 " " " " magnesium carbonate
- (b) 33.3 "parts by weight of sulphathiazole
66.6 " " " " magnesium carbonate
- (c) 50 parts by weight of sulphathiazole
50 " " " " sulphapyridine

Control Snuff:

- (d) Light magnesium carbonate.

To these 1% of menthol may be added according to individual taste. If children are to be treated it would probably be best to omit the menthol. The general impression obtained is that (b) and (c) are better than (a), but that (b) and (c) are equally effective.

The use of lycopodium powder was discontinued, as two of the subjects showed signs of apparent sensitization after a week or two. These signs—profuse rhinorrhoea and headache—disappeared when magnesium carbonate was substituted for the lycopodium. Dr. M. H. V. Cameron

(1941) directed attention to the possible danger of the lycopodium producing granulomata, and cited papers on this subject by Erb (1935) and McCormick and Ramsey (1941). Dr. Cameron is also of the opinion that magnesium carbonate might be a danger, as granulomata apparently due to the use of magnesium silicate have been described. It is probable, however, that when this reaction occurs it is not due to the magnesium ion but to the silicate ion.

Penicillin (1% in lycopodium powder), which had previously proved effective with the few subjects on whom it had been tried, was again tested at the same concentration but with magnesium carbonate powder as a diluent. In this form the penicillin was much less effective than it had previously been, and *in vitro* tests showed that in a few days the snuff lost its power to inhibit the growth of staphylococci. Prof. Florey states that penicillin is rapidly destroyed in an alkaline medium, and it is probable that there is a sufficiently destructive alkalinity on the surface of the particles of magnesium carbonate. Before the use of lycopodium was discontinued penicillin (1%) associated with sulphathiazole (33.3%) and lycopodium was tested on a few subjects, but was found to be no more effective than the sulphathiazole snuff alone.

Method of Taking the Snuff

The subjects have taken the snuff six times a day, either by the classic method or by sniffing it from one corner of a small folded triangular piece of paper. The amounts thus taken per day have been weighed. Twelve pinches or a day's supply of the sulphathiazole (33.3%) in magnesium carbonate weigh 0.075 gramme, representing an intake of less than 0.6 gramme of sulphathiazole a week. Similarly a week's intake of the sulphathiazole - sulphapyridine snuff weighs about 1.6 grammes. No toxic symptoms were ever observed, even after many weeks of snuff-taking.

Persistence of Snuff in the Nose

Study was made of the amount of sulphathiazole taken up by a nasal swab. Swabs from both nostrils of the 17 subjects were examined chemically about two hours after the last snuff-taking. In 11 out of 34 swabs sulphathiazole was demonstrated in amounts ranging from 0.03 to 0.39 mg. As the presence of the drug on the nasal swab might affect the bacteriological findings, all subjects were directed not to take any snuff during the twelve hours preceding swabbing, which was carried out at 10.30 a.m. After this instruction no sulphathiazole was demonstrated on the nasal swabs.

Results with Nasal Carriers of Staphylococci

All the 17 subjects under test were carriers of staphylococci: 3 were light but persistent carriers, whereas swabs from 14 yielded heavy growths of *Staph. aureus* or a coagulase-positive *Staph. albus*. These organisms were sometimes found together on the same plate.

In all cases except one the staphylococci were very greatly reduced as a result of treatment with sulphathiazole snuff, but they never entirely disappeared. Only one carrier was relatively resistant to the snuff in that the number of organisms found was but slightly reduced. In general, when the number of colonies found was small as a result of treatment the staphylococci were white and coagulase-negative, although small numbers of coagulase-positive white staphylococci and of *Staph. aureus* tended to persist in a few carriers. No carrier was definitely "cured." Two to three weeks after treatment was stopped heavy growths of *Staph. aureus* and coagulase-positive *Staph. albus* were again obtained. In a few instances the organism did not appear in profusion until between four and six weeks had elapsed.

Chart I illustrates the progress of one of these staphylococcus carriers. In all charts the counts from the right nasal cavity are represented by a continuous line, those from the left nasal cavity by an interrupted line. The ordinates represent the average of the weekly number of

remained clear till the investigation ceased four weeks later. In the remaining carrier, in spite of treatments with one or other form of sulphathiazole snuff for thirteen consecutive weeks, the bacillus returned four weeks after he ceased to take snuff. Chart II illustrates the case of a carrier in whom the organism reappeared between courses of treatment.

CHART I.—Carrier of staphylococcus.

SP = " " equal parts of sulphathiazole and sulphapyridine snuff.

staphylococcal colonies counted on the blood-agar plates after forty-eight hours' incubation. Counts of over 100 were recorded as > 100 , and are marked as 100 on the charts.

Results with Nasal Carriers of Hoffmann's Bacillus

Eleven of the 17 staphylococcus carriers also carried Hoffmann's bacillus. In every instance the bacillus disappeared directly after sulphathiazole snuff treatment was begun. The 10% sulphathiazole snuff was as effective as the others. With 7 of these carriers the organism, having

Results with Nasal Carriers of Pneumococci

The pneumococcus, so far as this investigation goes, seems to be completely resistant to every kind of snuff used in this experiment.

There were 9 subjects who carried pneumococci for varying periods. One carried the organism throughout the whole of the investigation, 3 carried it for only a short time, and from 4 the pneumococcus was first isolated about a week after the onset of a cold and disappeared after a few days or weeks. The ninth subject first had a pneumococcus in his nose during the third week of a cold and thereafter became a chronic carrier.

CHART II.—Carrier of Hoffmann's bacillus.

SP = " " equal parts of sulphathiazole and sulphapyridine snuff.

once disappeared after one course of treatment, was never again isolated even after many weeks. In 3 other carriers the organism returned in two to three weeks after the cessation of treatment, but after a third period of snuff the nose

CHART III.—Carrier of pneumococcus.

P = " " 1% penicillin in magnesium carbonate.
SC = " " 1% penicillin with 33.3% sulphathiazole in lycopodium.
SP = " " equal parts of sulphathiazole and sulphapyridine.

Two subjects who first showed pneumococci in a snuff-free interval continued to carry a pneumococcus in undiminished numbers, one for two weeks and one for four weeks, while taking sulphathiazole (33.3%) snuff. Another subject (see

Chart III) carried a pneumococcus during the entire investigation in spite of treatment with sulphathiazole (33.3%) snuff and sulphathiazole-sulphapyridine snuff. He was known to be a chronic pneumococcus carrier. Type III and other pneumococci having been isolated from throat and nose on many occasions over several years. Most of the swabs obtained during the present experiment grew Type III pneumococci, but sometimes a mixed growth of Type III and other pneumococci was obtained.

Two further subjects began to carry a pneumococcus while taking sulphathiazole (33.3%) snuff, and each continued to carry the organism for two weeks. Another subject began to carry a pneumococcus in the autumn of 1940, in the third week of a cold, while taking 5% proflavine snuff. He was later treated with sulphathiazole (33.3%) and sulphathiazole-sulphapyridine snuffs for thirteen consecutive weeks, but never lost the pneumococcus. The pneumococci isolated from these carriers were sensitive to sulphathiazole and sulphapyridine *in vitro*, which makes the failure of the snuffs to affect the carriage of this organism difficult to explain. It is possible that this organism tends mainly to colonize the sinuses and sinus cells and other inaccessible nooks and crannies in the nasal cavity.

Results with Other Organisms

Meningococci.—These organisms are not commonly isolated from the nose, and in this investigation the chance of obtaining a culture of meningococcus was small, because the swabs were emulsified in heart broth and the broth was then used to inoculate plates. Meningococci in heart broth may die in a few minutes. In spite of this, meningococci were isolated during January and early February from four subjects who were taking plain magnesium carbonate snuff. From one subject the organism was obtained only once, but from the other three it was obtained on three or four occasions during two weeks. After this each carrier started a course of sulphathiazole (33.3%) snuff, and the meningococci disappeared and were not seen again during the remaining weeks of this investigation, even during snuff-free intervals.

Haemolytic Streptococci.—One subject carried a haemolytic streptococcus (Group A, Type 5) in his right nostril only. It was grown from 19 out of 25 swabs during a period of ten weeks and did not disappear with sulphathiazole (10%) snuff treatment. Afterwards the carrier was treated with sulphathiazole (33.3% snuff) for seven weeks and then with sulphathiazole-sulphapyridine snuff. During the first three weeks of this treatment there were four positive swabs each yielding only one or two colonies. The organism then disappeared, and had not returned four weeks after cessation of treatment.

Neisseria catarrhalis.—There were five carriers of a Gram-negative coccus which did not ferment dextrose, maltose, or sucrose, and had dull grey-yellow colonies which could be easily pushed over the surface of the plate with a wire loop. Only one subject lost this organism when taking sulphathiazole (10%) snuff, and with him it never reappeared. Three others lost it during treatment with sulphathiazole (33.3%) snuff: with one of them it reappeared four weeks after stopping snuff. The fifth subject did not lose the coccus till treated with sulphathiazole-sulphapyridine, and it returned two weeks after stopping snuff.

Proteus vulgaris.—There was one carrier of this organism. Four swabs were all positive when he was first examined. It appeared less often under treatment with sulphathiazole (33.3%) snuff, and was grown from only one of eleven swabs during treatment with sulphathiazole-sulphapyridine snuff. After stopping snuff three out of seven swabs were positive. *In vitro*, *P. vulgaris* was only slightly sensitive to sulphathiazole even in saturated solution.

Antiseptic Snuffs in Relation to Colds

There is now further evidence from a number of people that the snuffs, if taken within two days after the onset of a cold, shorten the course of the disease. The discharge usually remains clear and the purulent stage is either prevented or lessened in intensity. There is no evidence that the snuff prevents colds.

Oral Insufflation of Antiseptic Powders

Three individuals were treated by the oral insufflation of sulphathiazole (33.3%) in magnesium carbonate. The

tonsils and visible part of the nasopharynx were thickly coated with the powder three times a day on five days a week, from Monday to Friday. No evidence was obtained, from swabs taken on Tuesday to Thursday inclusive, of any alteration in the type or numbers of organisms present.

Summary

An antiseptic snuff containing sulphathiazole is effective in causing an extreme reduction in the number of staphylococci in nasal carriers of this organism. The carriers are not cured, as the organisms reappear within a few weeks of the cessation of treatment.

It is effective in the cure of carriers of Hoffmann's bacillus and is likely to prove effective in the treatment of chronic nasal diphtheria carriers.

It may be effective in the treatment of nasal haemolytic streptococcus carriers.

It may be of value in the treatment of carriers of meningococci.

It is worth further trial in cases of the common cold, in which it tends to affect the course of the disease favourably although it is not a preventive.

There is no evidence that it affects the nasal carriage of pneumococci.

We wish to express our thanks to all those who have submitted themselves to repeated swabbings and snuff treatment over many months. We are also greatly indebted to Messrs. May and Baker, Ltd., for their generous help in supplying us with the sulphathiazole and sulphapyridine used in this and the earlier investigation.

JUGULAR THROMBOSIS AFTER TONSILLITIS

BY

R. L. FLETT, M.D., F.R.C.S.

Aural Surgeon, Derbyshire Royal Infirmary

Three cases of jugular thrombosis have been treated. A description of the condition is best given in the details of their clinical history.

Case I

A man aged 21 was admitted to hospital on November 8, 1934. Two weeks before admission he had had a quinsy without pus formation, and swelling below the left mastoid. The temperature was 104°. This responded to local antiseptic treatment. Then just before admission he complained of pain behind the right mastoid process, but no pain in the ear or deafness. There was some thickening over the area of the mastoid emissary vein. The temperature was normal. The tympanic membrane was congested but translucent. Paracentesis was performed and about two drops of serous exudate was obtained. The patient looked so ill, and his temperature had been so high with his throat condition, that a cortical mastoid operation was performed. The mastoid cells were practically normal except for some congestion, and no pus was obtained. The lateral sinus plate was so posteriorly placed that the sinus was not exposed. After a swinging temperature for five days the clean mastoid wound was reopened and a lateral sinus full of pus exposed. This was opened and the outer wall cut away. Bleeding was secured from the torcular but not from the jugular end. Packs were inserted, being removed after five days. Before the operation both optic disks showed about three dioptres of optic neuritis. The whole condition cleared up, apart from an attack of German measles, one month after the first operation.

A blood investigation showed 75% haemoglobin, and ferrous iron was administered in large doses. There had been no swelling in the neck at the time of the lateral sinus operation.

and a jugular operation was not thought necessary. The small amount of serous exudate in the middle ear was thought to be due to the proximity of an infected jugular bulb, and the lateral sinus infection was obviously of too long duration to be put down to the mastoid operation.

Case II

A woman aged 34 was admitted on April 4, 1940, with a lateral pharyngeal abscess below the tonsil at the level of the epiglottis. She had had pain for a week, and for three days acute difficulty in swallowing, with three rigors. Her temperature was 103° when first seen. She was five months pregnant. There was a hard brawny swelling from the left mastoid to the sterno-clavicular joint, the breath was very foul, and there was some respiratory distress. Swelling was present in the submental region.

Under local anaesthesia the left jugular vein was opened and about 30 c.cm. of foul pus obtained. The vein was packed with a thin gauze strip and the wound left open, with the vein edges sutured to the skin. The patient's condition improved, but two days after admission swallowing was almost impossible, and she regurgitated all fluids. Under local anaesthesia the inner wall of the previous incision was cut, and dissection carried through fibrosed tissue to the inner side of the carotid sheath. This was retracted laterally and the thyroid gland medially, and 20 c.cm. of foul pus obtained from a large abscess against the lateral pharyngeal wall. A tube drain was inserted. Her condition again improved, but the submental region became swollen and the floor of the mouth was raised.

Under local anaesthesia an incision was made from the chin to the hyoid bone and pus was obtained from an abscess extending laterally in both submaxillary regions to the angles of the jaw and down to the geniohyoids. The patient's general condition improved and temperature continued at a level of 99°. There were no further changes in the local condition and the whole neck remained brawny. However, three days after the last operation her temperature suddenly rose to 102° and pulse to 160, and the patient died in a cyanotic condition on April 10.

At necropsy the left side of the neck was hard and indurated, with small localized abscesses scattered throughout the muscles. The jugular vein showed thrombosis just below the opening above the junction with the subclavian. There was also a thrombosis in the lateral sinus on the left side. The cavernous sinus was normal.

Besides having the abscess opened, she had been given a large amount of sulphapyridine (intramuscularly when she could not swallow the tablets). The pus from the internal jugular vein showed numerous Gram-negative bacilli and diplococci, and a fair number of Vincent's organisms. On culture *Staphylococcus aureus* was grown. Her haemoglobin never fell below 85% and the leucocytosis varied between 26,000 and 22,000 per c.mm. In this case a more extensive operation should have been done at first—opening of the jugular, extension down the lateral wall of the pharynx, and dissection deep to the submaxillary gland.

Case III

A woman aged 54 was admitted on March 6, 1940, with a history of sore throat for one week, a temperature of 104°, a quinsy on the left side, and a large brawny swelling on that part of the neck. With local treatment and sulphapyridine the condition in the throat cleared up and the temperature was normal in two days. There was still some swelling below the left mastoid, and the patient's temperature was reduced to 101°. At this time her haemoglobin was down to 55% and red cells to 3,000,000; leucocytes were 21,000 per c.mm. On March 19 her temperature rose to 106°; a blood culture was negative, but next day the left internal jugular was opened low down in the neck and pus containing pneumococci and streptococci was evacuated.

The patient's condition now showed some improvement, but she tended to have breathless attacks at times. The pharynx and larynx appeared normal, but on examination of the chest crepitations were found at the right base and radiographs revealed some dimness of the lower half of the right lung. Three blood transfusions were given at weekly intervals. The sulphapyridine was stopped and sulphanilamide was given in regular doses over three weeks. The pulse rate showed a steady

rise and the respiration rate at times was over 40. On April 14 the jugular vein was opened up to the mastoid process and down to the sterno-clavicular joint. Blood clot was obtained but no pus. There had been some question of the thrombosis spreading to the subclavian vein, but the condition of the patient was too bad to warrant operation on this or to expose the lateral sinus.

However, on April 17 symptoms of cavernous sinus thrombosis appeared and the patient died next day. A few hours before death she coughed up 3 oz. of bright blood. As a necropsy was not allowed the source of this could not be ascertained, but was probably the right lung. This loss of blood was not of much consequence, as two days previously her haemoglobin was up to 92%.

Summary of Literature

Several writers have reported cases of this condition, but a description of it seems to have evaded the textbooks. Most of the articles were in the American literature, but van Gilse and Benjamins, in personal communications, have described cases to me. On the Continent drainage of the internal jugular vein has apparently been sufficient, but some of the American surgeons have found it necessary to open and drain both the internal jugular and the lateral sinus. This, I think, should have been done in my last two cases, but of course the second patient was too ill to withstand any further surgical endeavour.

The cases recorded in the United States certainly give better results than mine. Stone and Berger (1936) report two of their own with recovery, two of Eagleton's, and one of Kerman's. Out of five there were three recoveries, in each of which cases the neck and lateral sinus were operated on. Porter (1937), in reporting his case, is also of the opinion that this should be done. Gilmore's case (1939) recovered after only the jugular operation. Beck (1934) seems to favour this, but he had one case in which the lateral sinus was opened because of mastoiditis. Nussbaum (1929) collected 58 cases with 23 recoveries up to 1927, so it may be seen from the literature that the condition carries a high mortality.

Discussion of Treatment

Points in the treatment may be summarized as follows:

1. The operative treatment must not be delayed until a positive blood culture is obtained. Rigors may not occur; sometimes there are feelings of chill.
2. If the external swelling does not begin to subside one day after satisfactory incision of an abscess in the pharynx external operation is necessary.
3. If the condition of the patient does not improve after the internal jugular is opened, drainage of the lateral sinus should be performed. Only about four days should be allowed for this improvement.
4. As regards the sulphonamide group, the last two cases had large amounts of sulphapyridine before operation, and it was noticed that any abscesses found were walled off by strong fibrous-tissue capsules, which made the dissection in the neck very difficult. Also the pus in these abscesses seemed to be thick and semi-organized by fibrin deposits. At necropsy the second case showed muscles and neck contents bound together with small abscesses scattered in the hard fibrous mass almost like actinomycosis. It seemed to me, therefore, that it would be more reasonable in a case that was likely to require opening of abscesses in the neck, especially abscesses among muscles and fasciae, to retard the administration of these drugs until the abscesses could be opened, and opened widely. As Beck (1932) states: "In cervical fascia infections drainage placed in advance of involvement is better than drainage which only trails the involvement." From consideration of these two cases it is my impression that pre-operative treatment by the sulphon-

receiving treatment in this hospital are secondarily infected, and the majority of those have received treatment with sulphur before admission.

The therapeutic agent now employed is an oil-in-water-type emulsion of benzyl benzoate prepared with triethanolamine from the following formula:

Benzyl benzoas	33.3
Ac. stearic.	2.5
Triethanolamine	0.5
Aq. dest.	ad 100.0

Dissolve the stearic acid in the benzyl benzoate with the aid of gentle heat. Cool to 38° C. and add the triethanolamine dissolved in half of the water. Shake to emulsify and gradually add the remaining water, shaking after each addition.

It has been found that the temperature of preparation considerably affects the stability and viscosity of the emulsion. The product described here showed no separation when placed in a refrigerator for six hours at 0° C.; and when incubated for six days at 37° C. there was slight separation, but it immediately re-emulsified on shaking. Emulsions prepared at higher temperatures were not so stable. The routine of benzyl benzoate treatment as described by King (1940) was followed. It was hoped to confine the treatment to one application, but some cases have required two or more.

Results

The cases so far treated by this method number 39, and they must be divided into three groups:

- I. Primary non-infected scabies (23 cases).
- II. Secondarily infected scabies (5 cases).
- III. Secondarily infected scabies which have failed to respond to earlier treatment (11 cases).

All cases were examined daily for at least one week following completion of treatment. Owing to the degree of secondary infection many remained under observation for a much longer period.

The number of applications found necessary are shown in Table II.

TABLE II

Group	No. of Cases	No. of Applications						Results
		1	2	3	4	5	6	
I	23	18	2	3				No failures
II	5	3		1		1		" "
III	11	4	2	4			1	" "

78% of the primary non-infected type and 42% of the secondarily infected cases were cured with one application. There were no failures in the non-infected cases, but 25% of those secondarily infected did not respond to this treatment. The failures had all been previously treated unsuccessfully with sulphur ointment, but were ultimately cured by mitigal, or dimethyldiphenylene disulphide (C.I.).

Conclusions

We feel that the importance of using a paste in place of an ointment in the treatment of impetigo is not fully realized or sufficiently emphasized. It is also considered that the substitution of a fat-soluble aniline dye in place of the time-honoured ammoniated mercury is a step forward in treatment as well as a justifiable wartime economy.

The use of a stable emulsion we feel is of advantage in the treatment of scabies. The emulsion is easy of application; only one-third of the amount of benzyl benzoate is required for a treatment as compared with the commonly used mixture of soft soap, alcohol, and benzyl benzoate; and the danger of irritation and therefore of secondary infection is reduced to a minimum. Finally, the stability

of the emulsion is of undoubted value in the Services, where varying temperatures are encountered.

Summary

It is suggested that a fat-soluble form of brilliant green might replace mercury in the treatment of impetigo.

It is stressed that a paste might with advantage be used in place of ointment in the treatment of impetigo.

A stable emulsion of benzyl benzoate is advocated for the treatment of scabies, and it is noted that this would result in a saving of benzyl benzoate, as only one-third of the normal amount is required.

We are indebted to Surgeon Rear-Admiral Sankey for permission to publish this paper.

ROOT VEGETABLES AS ANTISCORBUTICS IN INFANT FEEDING

BY

D. M. MATHEWS, B.Sc., F.I.C.

AND

A. L. BACHARACH, M.A., F.I.C.

Any shortage of citrus fruits presents a special problem in the feeding of infants and very young children, especially the former, who cannot obtain their supplies of ascorbic acid to any appreciable extent from potatoes or leaf vegetables. Published work, as summarized in the tables of Fixsen and Roscoe (1938, 1940), indicated that the turnip should be a useful source of ascorbic acid. It was decided to make a preliminary investigation of the root vegetables, turnip (*Brassica rapa*), swede (*Brassica campestris*), and parsnip (*Pastinaca sativa*)*. The samples were bought in the open market or picked from crops raised in private gardens from commercial seed in December, 1940, and January, 1941. After our completion of some exploratory work the extensive paper of Chappell (1940) appeared. Our results were in good accord with hers, which were themselves in agreement with those of Olliver (1936, 1940); moreover, the scope of the investigations made by these workers had exceeded ours, so that the separate publication of most of our figures might seem unnecessary. However, the relevant figures published by Olliver and Chappell were concerned with the whole raw vegetables or with the effect of domestic culinary procedure upon the amount of ascorbic acid derivable from them, whereas we were primarily concerned with preparing from the roots something that could be fed direct to the very young; it seems permissible, therefore, to summarize our results and conclusions.

Ways of using Root Vegetables

There are at least three possible ways of using these root vegetables in infant feeding: they will be considered in turn. First, it has occasionally been suggested that the chopped roots should be covered at night with fine sugar, and that any juice separated by next morning could be used as an antiscorbutic. We found that this procedure

* Dr. J. C. Drummond, scientific adviser to the Ministry of Food, expressed interest in the problem, and urged us to look into the matter; the analyses were all carried out by one of us (D. M. M.), with the permission of Mr. A. F. Lerrigo, head of the analytical department of Glaxo Laboratories, Ltd., to whom we wish to express our gratitude.

resulted in negligible extraction of ascorbic acid—about 0.02 mg. per c.cm. (cf. Dr. K. E. Barlow, *Journal*, 1941, 1, 797). On physico-chemical grounds we had regarded as suspect the apparently almost miraculous properties attributed to sucrose as an extractant of ascorbic acid.

Secondly, the grated vegetables were simply squeezed through muslin; juices containing 0.30 mg. and 0.32 mg. of ascorbic acid per c.cm. were thus obtained from swedes and turnips respectively. It might, however, be thought by some that such expressed juices would be unfit for infant feeding unless sterilized by boiling; moreover, the effect on the ascorbic acid content of any ascorbic oxidase present might be significant if the expressed juices were allowed to stand. Boiling would of course destroy any enzymes present. We therefore examined the effect of boiling on the squeezed-out juice. When boiled for periods up to fifteen minutes, and whether brought to the boil slowly or quickly, the juice showed no destruction of ascorbic acid. Prolonged boiling—for thirty minutes or more—sometimes produced slight losses. Exposure to the atmosphere in covered beakers without agitation produced no losses in three to six hours, and up to 25% loss in twenty-four hours; if, however, the juice was agitated (stirred) periodically the loss was more rapid and might amount to 75% in twenty-four hours. We conclude, therefore, that expressed juice can safely be boiled for a few moments and can be kept (whether unboiled or boiled) for several hours, provided it is covered and not vigorously stirred, without any serious loss of antiscorbutic activity.

Thirdly, the roots can be sliced and boiled with a little water, the cooked mass being then squeezed through muslin into the cooking water. The concentration of ascorbic acid in the resulting liquor will naturally depend on the amount of water used, among other things. Even when this was reduced to a minimum—just enough to cover the vegetables—the liquors were less good sources of ascorbic acid than the cold-pressed juices discussed above. Nevertheless both swede and turnip yielded liquors containing from 5 to 16 mg. of ascorbic acid per 100 c.cm. The comparison between the cold-pressed juices and the cooked liquors

Results

As a matter of interest we have summarized in the accompanying table the recent results obtained by Olliver and Chappell, as well as our own, along with some figures for orange juice and blackcurrants. All our determinations were made by titration with 2:6-dichlorophenol-indophenol in the presence of trichloroacetic acid.

Parsnips appear to be of no more use than carrots as sources of ascorbic acid. On the other hand, turnip juice or swede juice, cold-pressed, before or after boiling, or the liquors from squeezing the lightly boiled roots, should be of value, especially in infant feeding. Taking the daily requirements of an infant as 5 to 10 mg., then from 1 to 2 fl. oz. of turnip juice or 1/2 to 1 fl. oz. of swede juice each day would suffice. Either of these juices, since they are only slightly acid, can be used to replace the boiled water of a milk feed without causing any curdling, though it imparts to the product a distinct taste and odour of the vegetable, that from the swede also contributing a little colouring matter.

Medical Memoranda

100 Cases of Scabies: A Comparison of Treatments

To investigate the relative efficiency, speed, cost, and convenience of the various treatments of scabies recently discussed in the *British Medical Journal* I have treated men suffering from this complaint by five different methods:

1. *Sulphur Ointment*.—Sulphur ointment 10% is applied after a hot bath and a scrub in the morning; another application of the ointment is made in the evening.

2. *Sulphur Ointment and Confection of Sulphur*.—The same as the above, except confection sulphuris 1 drachm is given once daily (Berneville, 1941).

3. *Benzyl Benzoate*.—Anoint the body with soft soap. Soak in a hot bath, rubbing the affected areas thoroughly. While the body is still wet apply a lotion consisting of equal parts of benzyl benzoate, industrial spirit, and soft soap (King, 1940) vigorously all over with a nail-brush for five minutes. Allow it to dry, then apply the lotion again for a further five minutes. Dry with a towel.

4. *Rotenone*.—A hot bath is taken and the patient is painted all over with 1% rotenone B.D.H. or 2% rotenone (sarevan) Evans in front of a fire (Callor, 1941).

5. *Derris Root*.—The patient is painted thrice daily with a solution consisting of 4 oz. of derris dusting powder, 18 drachms of soap flakes, and 1 gallon of cold water (Saunders, 1941).

There was no selection of cases apart from the exclusion of those in which the diagnosis was in doubt. Each case was treated by one method only until cured.

The diagnosis was founded on the association of itching when warm with the presence of burrows, which are most profuse in certain areas and there give rise to a red papular rash. A patient was considered cured when the itching had ceased, when there was no sign of activity of the rash (redness, swelling, etc., around the burrows), and when the rash had ceased to spread. It is probable that in this series about five days were wasted by hysterical or wilful "prolongation."

RESULTS AND COST

The time taken to cure 20 cases was: method 1, 46 days; method 2, 59 days; method 3, 30 days; method 4, 38 days; and method 5, 41 days. I account for the fact that the 20 cases

must not be carried too far; different samples of vegetables were used at different times in the year; and no properly controlled comparison was carried out in this purely preliminary investigation. Our results indicate, however, that cooking, because of the inevitable dilution of the juice and possibly also owing to some destruction, gives a solution of ascorbic acid somewhat less concentrated than the raw or cooked cold-pressed juice, but still a very useful antiscorbutic for use in infant feeding under present conditions.

treated by sulphur ointment took only 46 days as being due to the large number of mild cases in that group.

In assessing the cost, the expense of disinfecting the clothes and blankets is ignored because it varies so much from place to place. The cost of the soft soap for bathing purposes and the soap flakes is also ignored, it being very small. On this basis I calculated that the cost of curing a case by the five methods was: (1) 4.44d.; (2) 6.79d.; (3) 11.25d.; (4) 24d.; (5) 0.25d.

CONCLUSIONS

Benzyl benzoate is the most rapid of the five methods tried. It is clean, but dermatitis results in some cases. Moreover, it is fairly expensive and, at the present time, is difficult to procure.

Diarrhoea is the only appreciable difference that confection of sulphur makes to a man already being treated with sulphur ointment. It has no effect on the time taken to cure him. Sulphur can be counted on to cure the average case in three days. It is reliable and cheap, and only rarely causes dermatitis. The drawback is that it is such a dirty method.

The rotenone preparations, which cure an average case in two days, are clean and convenient but very expensive. In three cases there developed dermatitis of the scrotum following treatment with rotenone; one of these also developed balanitis.

The derris root method is most satisfactory. It is extraordinarily cheap. It is also clean and efficient. There is no necessity for the patient to bathe or to disinfect the clothing he is wearing. I had no case of dermatitis following the use of derris root.

My thanks are due to S.B.P.O. Mellish and Surgeon Captain I. McA. Holmes.

Convulsions under Anaesthesia

Reports of the occurrence of so-called "ether convulsions" have become very frequent in the last few years, and one of the most anomalous features of this puzzling phenomenon is the apparent fact that, whereas a few anaesthetists or surgeons are able to recount a series of cases, the majority of anaesthetists have yet to meet their first case. The following describes my first experience of this alarming condition in fifteen years of anaesthetic practice, and I hope it will be my last.

CASE REPORT

The patient, an otherwise normal female child aged 10, underwent Steindler's operation upon both feet on June 11 last. Anaesthesia, administered by myself, was smooth and uneventful. The child received premedication with omopon 1/6 grain and scopolamine 1/300 grain one and a half hours before operation; induction was with nitrous oxide and oxygen, and after "blind" intubation anaesthesia was maintained with vinesthene 25% in ether in closed circuit, using a circle absorber. The child had been anaesthetized previously, at the age of 5, for tonsillectomy, the anaesthetic on that occasion being ethyl chloride followed by open ether. This anaesthesia is reported to have been without incident.

The temperature upon the evening preceding the Steindler operation was 99°; upon the day of operation it was normal. There was intermittent fever, rising to 100°, for two days after her operation; but this subsided, and for the succeeding four days the temperature was normal. On the seventh day pyrexia returned, accompanied by complaint of pain in the right foot. Pyrexia was intermittent, but since the pain persisted it was decided to change the plasters, and on June 25 I was asked to anaesthetize the child for this purpose. The evening temperature on the 24th was 101°, but on the morning of the 25th it was 98.4°. The child was not obviously ill or toxic.

Premedication was again with omopon 1/6 grain and scopolamine 1/300 grain. Induction with nitrous oxide and oxygen was smooth, and was followed by maintenance with vinesthene 25% in ether in closed circuit with circle absorber. Intubation was omitted, since upon this occasion the prone

position was not required. The day was hot and sultry, the theatre temperature, in spite of all available ventilation, being 82°. Within the first fifteen minutes of maintenance the respirations became more vigorous than normal, and it was found that the soda-lime in the absorber had become exhausted; this was therefore renewed. Respiration, however, continued to be unsatisfactory, resolving itself into a series of sudden diaphragmatic contractions resembling hiccup, unwarranted by the plane of anaesthesia (lower first plane), with accompanying slight cyanosis. Rhythmical distension of the lungs by gentle bag compression improved the colour and temporarily allayed the diaphragmatic spasms, but these returned, and were shortly followed by generalized convulsions, with twitching of the facial muscles and intense cyanosis. The nature of the condition now being apparent, I withdrew the anaesthetic, raised the head by placing the table in reverse Trendelenburg, instituted lung inflation with oxygen, and ordered some 10% evipan solution to be prepared and a rectal temperature to be taken. The rectal temperature, taken under great difficulty, was recorded as 103°; the child, however, was extremely hot to the touch, with a dry skin. No improvement in the condition being apparent, I decided to give the evipan. Venepuncture proved to be impossible owing to the absence of visible or palpable veins, and since the condition of the child now appeared to be desperate I gave 4 c.cm. of the evipan intramuscularly into the triceps. The patient was now grey-black, with pupils widely dilated and arrested respiration. I rapidly exposed the larynx, passed an intratracheal catheter, and began insufflation with oxygen. This measure quickly restored the colour. No further convulsions occurred, and the operation, which had revealed a septic condition of the wound of the right foot, was completed, and the legs were re-encased in plaster without additional anaesthetic. No further trouble occurred, and the child left the theatre with normal respirations. Next day she was quite well.

COMMENTARY

Of the usually cited causative factors the following were present in this case: sepsis and possibly some toxæmia; an abnormally hot theatre and sultry weather; raised CO₂ tension for about fifteen minutes, due to exhausted soda-lime; a patient partially covered with mackintosh sheets; the administration of ether. The following factors were absent: the pre-operative administration of atropine; suboxygenation; marked toxæmia.

While the comparative rarity of the occurrence of convulsions under anaesthesia would seem to postulate the need for some subtle and rare combination of factors in their production, it is clear from the cases reported that only two of the factors cited are constantly present—sepsis with toxæmia, and anaesthesia in some form. Of these two factors, since cases have been reported as having occurred under both local and general anaesthesia, which differ widely in the physiology of their actions, it would seem that sepsis with toxæmia is the more constant and must therefore be accorded pride of place in causation; while anaesthesia must be relegated to the role of precipitating factor, possibly through a modification of the stimulus threshold of the nervous system. This would seem to support strongly the postulated neurotoxic origin of the condition.

I have complete confidence in the advisability of administering evipan in this condition, whatever the state of the patient; and from the rapidity and efficacy of its action in this case it would seem that the intramuscular route is as effective as any other, and, if one may dogmatize after such brief experience, I would advise the adoption of this route, since it would seem to be safer in a moribund patient and to afford a longer period of less depressive sedation. As an alternative technique I would suggest a minimal effective dose intravenously, followed after a short interval by the formation of an intramuscular "depot."

CONCLUSIONS

Of all the possible causative factors so far cited only two are constantly present in every case.

Although the convulsions do not necessarily start in the facial muscles, as has been so often stated, there is not the slightest difficulty in recognizing the condition once it has arisen.

Successful treatment consists in the immediate withdrawal of the anaesthetic, the early administration of evipan, intra-

muscularly, intravenously, or by both routes, and the immediate institution of intratracheal insufflation with oxygen.

No anaesthetist should approach a young and febrile patient unless he has the means and the ability to adopt these measures at a moment's notice.

Complete Stenosis of Common Bile Duct: Operative Cure

This case is an example of the successful treatment of a condition which is otherwise invariably fatal. It is presented in the hope that it will help to draw attention to the possibility of cure in such cases.

CASE HISTORY

A woman aged 53 was operated on by Mr. Clark at the North Riding Infirmary, Middlesbrough, on May 8, 1939, for gall-stones. An ordinary cholecystectomy was done, but it was noted that the gall-bladder was very adherent to the liver. The common bile duct contained no stones and was not opened. There was no unusual difficulty about the operation, convalescence was normal, and the patient was discharged on July 6, 1939.

Four months later, on November 7, she was readmitted with progressive jaundice and severe pruritus, and on December 5 a second operation was done. The region of the common bile duct was seen to be a mass of dense scar tissue; the duct itself could not be found in spite of careful dissection. As there seemed no prospect of successful treatment the abdomen was closed. The patient's condition became steadily worse, the itching driving her almost mad, and it was obvious that unless something could be done, and that quickly, she would shortly die. In the meantime Wakeley (1939) had described the successful treatment of such a case by incising the liver and duodenum and stitching a rubber tube in place between them, covering the anastomosis with omentum. It was decided to carry out this procedure.

On February 27, 1940, her abdomen was opened for the third time and the operation described by Wakeley performed. The incision into the lower surface of the liver was deepened by blunt dissection to a depth of 2½ inches, using a pair of artery forceps. The patient recovered well from the operation, but for a week there was no improvement in her jaundice or pruritus. Then quite suddenly she began to pass normal-coloured stools and the itching disappeared. Her jaundice began to improve about the same time, but more slowly. She was discharged on April 23, 1940, with only an icteric tinge, feeling very well. A radiograph at that time showed the tube to be still in position. She occasionally passes clay-coloured stools and has some slight skin irritation, but when last seen at the out-patient department on February 10, 1941, her stools were normal, although she still had an icteric tinge. A radiograph taken on August 12, 1940, showed that the tube had disappeared, presumably having been passed per rectum.

DISCUSSION

One interesting point which arose was whether the incision into the liver should be deepened by sharp or blunt dissection. In this case it was done by the blunt method. I have since been informed by Surgeon Rear-Admiral Wakeley that in his case he dissected down through the liver substance with a scalpel until he found a distended bile duct; he opened this and inserted the tube. This is not made quite clear in his description of the case. In the present case it seems likely that after a week the rubber tube eroded a distended bile duct in the liver substance, and thus allowed drainage. It is not surprising that this should happen, as in a similar case, not operated on, a bile duct has actually been known to rupture through the diaphragm and open into a bronchus (Miller, 1939). With this in mind blunt dissection would seem to carry less risk of serious haemorrhage.

I am indebted to Mr. J. C. Clark, the surgeon in charge, for permission to publish the case, and also wish to thank Surgeon Rear-Admiral Wakeley for his encouragement to do so.

Reviews

HISTORY OF PHARMACY

History of Pharmacy. A Guide and a Survey. By Edward Kremers, Ph.D., Sc.D., and George Urdang, D.Sc. (Pp. 466: 30 illustrations. 25s. net.) Philadelphia, London, Montreal. J. B. Lippincott Company. 1941.

This typically encyclopaedic German-American work is stated by the authors to be compiled with particular reference to the needs of students. We can hardly believe that, however useful it may be as a book of reference, students can or ought to try to assimilate such a mass of detail. The opening chapters on early backgrounds and medical theories are, however, of real general interest. They are followed by sections dealing with the rise of professional pharmacy in different European countries, and here we detect a mildly patronizing attitude towards England. Nearly half the book is devoted to a minutely documented account of pharmacy in the United States in all its bearings. A bibliography, chronology, and glossary complete this monument of laborious industry.

Certain general conclusions emerge. The authors believe that from the very beginning attempts at rational therapeutics went hand in hand with purely magical procedures. Secondly, it appears that the repeated attempts of the physician to control the pharmacist have not always favoured the scientific advance of pharmacy. It is interesting to learn that the Emperor Frederick II, that extraordinarily modern-minded man, issued an edict in 1240 separating the pharmaceutical from the medical profession. In this country the Society of Apothecaries had in 1617 to emancipate themselves from the physicians on the one hand and the grocers on the other. Then the apothecaries claimed to be practitioners of medicine, and to protect the interests of pharmacy the Pharmaceutical Society was founded just a century ago. Even so the struggle continues between the doctor who dispenses and the chemist who prescribes. Fortunately, a *modus vivendi* between the two professions concerning the *British Pharmacopoeia* and many other matters has been achieved.

The third point is that, although an increasingly high standard of education is demanded of the pharmacist, his privileges stand in danger of serious curtailment through the increasing power of the co-operative societies and patent medicine vendors, on both of whom the legislature casts a curiously protective eye, not to mention the wholesale chemist who sends out remedies all ready to be handed over the counter by a highly trained dispenser. The moral of the history of pharmacy is that if its professional status is not safeguarded the whole technique of healing suffers.

ENCYCLOPAEDIA OF MEDICAL PRACTICE

The British Encyclopaedia of Medical Practice, including Medicine, Surgery, Obstetrics, Gynaecology, and Other Special Subjects. Under the general editorship of Sir Humphry Rolleston, Bt., G.C.V.O., M.D. Publishing Editor, Adam Clark, L.M.S.S.A.; Sub-editor, G. Faulkner, D.Sc. *Surveys and Abstracts and Cumulative Supplement, 1940.* (Pp. 956, and pp. 283. No price given.) London: Butterworth and Co. (Publishers) Ltd.

Continuing to fulfil the plan originally adopted for the *British Encyclopaedia of Medical Practice*, the editors have brought out the 1940 volumes of *Surveys and Abstracts* and of the *Cumulative Supplement* in spite of wartime conditions. These keep the high standard previously remarked on. Though naturally influenced by both war problems and war needs, the contributors take a broad-minded view of the subjects under comment and again set out an up-to-date review of the matter. In the past few years two

advances in medicine have followed the elaborate and often apparently academic researches of the biochemists, and now the medical practitioner is reaping the benefit of all this work in finding great help in diagnosis from the use of chemical tests, and in treatment from the use of the sulphoamide compounds and the sex hormones. All these are now sufficiently established to have clear indications for their administration and something like reliable standards of efficacy.

The *Cumulative Supplement* is meant to elaborate and add to the information already available in the main body of the *Encyclopaedia*. With the new *Index* it is possible to find one's way to the discussion of the particular subject sought. The *Index* has been produced with the help of those accustomed to the control and running of medical libraries, and we find on testing that it enables a quick and satisfactory reference to the required information to be made.

In the volume of *Surveys and Abstracts* the editors have invited leaders in the various subjects discussed to give a summary of recent work. These articles give, therefore, digested reviews of the present aspects of medicine, surgery, and obstetrics, with special discussions of many of the systemic diseases, and most useful surveys of radiography and radiotherapy, chemical pathology, anaesthetics, and recent developments in drug therapy. The abstracts are remarkable for the breadth and variety of references to current medical literature from the medical profession of the world. In these times of stress and lessened supply the publishers have kept up the standard of production, so that the present volumes align themselves with those already printed before the war.

INTRODUCTION TO PHYSIOLOGY AND ANATOMY

Physiology and Anatomy. By Esther M. Greisheimer, M.A., Ph.D., M.D. Fourth edition. (Pp. 822; 474 illustrations, of which 52 are in colour. 18s. net.) Philadelphia, London, Montreal: J. B. Lippincott Company.

The popularity of this book is well attested by its having reached, since June, 1932, a fourth edition, and by the fact that reprints of all the earlier editions have been required. The subject-matter has been now arranged on what is termed the "unit plan," and the wide scope of the work is indicated by the headings of these units: (1) "The Body as an Integrated Whole"; (2) "The Erect and Moving Body"; (3) "Integration and Control of the Body by the Nervous System"; (4) "Maintaining the Metabolism of the Body"; (5) "The Reproductive System." The last includes an "Introduction to Embryology" and notes on pregnancy and parturition. The description of each subject is followed by brief allusions to practical considerations, and by a summary. The book is amply and well illustrated, the figures including some excellent x-ray photographs, and some useful schemes and tables which summarize recent work on such subjects as water balance, digestion, and the ovulatory cycle.

It may be freely admitted that the present work "reflects the most recent trends and concepts in the teaching of physiology and anatomy." One of these trends is greater attention than heretofore to the study of the physico-chemical side of physiology, which is all to the good. Other tendencies are, however, to reduce the period allotted for the study of anatomy and embryology. This trend has now moved so far that the description of individual muscles or the complete development of particular organs or parts is replaced by schematic tables or general statements which are wholly inadequate for the proper comprehension of these subjects from the standpoint of a medical practitioner. Dr. Greisheimer's book presumably fulfils the

requirements of the modern school of thought, and apart from the above comments the author is to be congratulated on the amount of useful information she has succeeded in putting before the reader in an attractive and interesting manner. From the physiological aspect the book should prove valuable not only to students training for the nursing profession but also to teachers of elementary applied or clinical physiology.

Notes on Books

We have received from Moscow, after three months in transit, a copy of a small book, *Health Resorts of the U.S.S.R.*, being a group of illustrated articles compiled from data in the Central Institute of Balneology under the editorship of Dr. I. A. PERTSOV. In his preface Prof. I. A. Valedinsky brings to light the boundless resources for the development of health resorts in the Union of Soviet Socialist Republics. "Innumerable and varied mineral springs and deposits of medicinal muds, peats, etc. are to be found literally throughout the whole of the Soviet Union." The numerous health resorts are recognized as forming part of the national wealth, and their development has proceeded according to the general State plan. Spa treatment also comprises one of the links in a chain of medico-prophylactic measures for improving the health of the working population of Russia. The book is published by the U.S.S.R. Society for Cultural Relations with Foreign Countries (Bolshaya Gruzinskaya, 17, Moscow, 56). Not many copies are likely to reach this country just now, but those that do will be read with particular interest by balneologists and climatologists.

Preparations and Appliances

TRANSFUSION PANNIER

A transfusion equipment with some special features of interest is now in use in the hospital and ambulance service of the Australian Army. Although not on sale in this country, it is on exhibition by Drug Houses of Australia Export Ltd., Australia House, London, W.C.2, and there are hopes that in course of time it may become standard British equipment. In designing the apparatus, which bears the trade name of "Solvac," assistance has been given by the Walter and Eliza Hall Institute of Medical Research, Melbourne.

The pannier in which the whole equipment is contained is a masterpiece of packing. For use in the field it is made of cane, covered with canvas, and it contains four litres of 5% dextrose in normal saline, a similar quantity in Ringer's solution, and two litres of normal saline, making ten litres of fluid suitable for intravenous administration, all vacuum-packed in screw-top flasks. There are also five sets for giving these solutions, each set comprising 5 feet of rubber tubing with clamp and dropper, and two glass cannulae with one No. 17 needle for alternative use. Five blood filters for addition to these sets when giving stored blood or blood containing clots are provided. There are two sets for collecting blood from donors. Each set comprises a sterilized bottle, stopper, two spare needles, air filter, 18 inches of rubber tubing fitted at each end with a blood needle of large bore, and a number of ampoules of anti-coagulant solution. Special attention is called to the design of the bottles and the method of closure. The bottle is graduated from both top and bottom and is of one-litre capacity. A metal bail fitted to the base enables it to be hung up by string or hook during delivery of contents. The bottle is closed by a rubber stopper pierced by two holes, one hole accommodating an air-inlet tube and the other being vacant. The stopper is covered by a rubber disk and this in turn by a metal disk, with elaborate precautions for accurate fitting, so that a hole in the disks exactly overlies the vacant hole in the stopper. Both disks are held in position by a metal collar, which screws on to the bottle neck.

The pannier also contains sets for grouping blood, various accessories and spare and alternative parts, and a useful feature of it is that every item is in a box carrying a plainly marked inventory label and showing also how many items of the same kind are included.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY AUGUST 16 1941

TREATMENT BY HYPOTHERMIA

About two years ago Prof. Temple Fay and Dr. Lawrence Smith of Philadelphia issued their first clinical report on the effects upon cancer growth of a general lowering of the body temperature by about 10° F. They termed this general depression of body temperature "hibernation," while local cooling of a tumour was called "refrigeration." This earlier work has already been reviewed in our columns.¹ A group of workers at the Lenox Hill Hospital, New York, reinvestigated the effects of this method of general cooling, but called it "cryotherapy." A third careful research has appeared under the authorship of Dr. J. H. Talbot² of Boston, and he has introduced the term "hypothermia," which on the whole seems more satisfactory and comprehensive than any of the other terms. He has reviewed the literature and points out that the local application of cold for treatment of cancer dates back as early as 1865. Recent studies have shown that regressive changes in tumours are most obvious when local hypothermia can be carried out at a temperature between 40° and 50° F. Special fitting coils through which a refrigerant circulates are applied and necrosis of tumour tissue may follow. Dr. A. McCravy³ has reported favourable results with local hypothermia in five cases of carcinoma of the bladder in which the bladder cavity had been marsupialized and exteriorized. In all cases the patient's life was prolonged beyond that expected for a patient not treated with hypothermia. It is possible that radiation combined with cold might be more effective than either alone, as the effects of cold upon the tumour cells are not so unlike those of radiation with x rays. Talbot emphasizes that hypothermia is not looked on as a cure for cancer by even the most sanguine of its advocates, yet it does have a place in the treatment of a selected group of patients suffering from this disease. The Lenox Hill Hospital authorities publish a list of cases which are unsuitable for treatment by general hypothermia; it needs more careful consideration than does the local therapy.

Contrary to what has been taught hitherto, the lowest internal temperature that man can bear probably lies somewhere between 70° and 75° and not between 90° and 95° F. Two patients of Talbot and his colleague Tillotson had rectal temperatures of 74° and 75° F. respectively, and both made an uneventful recovery from this cooling. The heat regulatory mechanism presumably ceases to operate below 75° F. in animals, and the continued fall in body temperature proceeds at the same rate as that in a dead animal in similar circumstances.

If the animal is then warmed the thermal regulatory mechanism begins to assert itself at approximately 75° F. In the hibernating animal the body temperature may approach 32° F. without causing death.

For induction of general hypothermia Talbot recommends three or more grains of nembutal intramuscularly twenty minutes before the patient is placed nude in the cold environment at 32° F. Just before the cooling 0.5 to 0.7 gramme of evipan is given intravenously. Within an hour the anaesthetic effect of evipan has worn off and simultaneously the body temperature falls. The anaesthetic property of the cold usually obviates the necessity for further intravenous anaesthesia or sedative. By keeping the environmental temperature below 60° F. a working range for internal temperature (controlled by rectal thermocouple) between 80° and 90° F. is maintained for not more than twenty-four hours in the trial period of treatment. This trial period is especially necessary for patients older than 40 or who have metastatic cancer. Following the initial treatment there may be one or more additional periods of from two to four days each, while the intervals between successive treatments may be as short as two or three weeks. It is not known how many times the treatment may be repeated. A gradual restoration of body temperature at a rate not higher than 2° F. an hour is associated with fewer ominous signs than a rapid rise. No serious after-effects have been observed, but the development of pneumonia in patients with metastatic cancer in the lungs is sufficiently common to cause rejection of such patients for treatment. During hypothermia there are various changes such as initial rise of pulse and blood pressure followed by a gradual fall, obliteration of venous channels, constriction of large arteries but no vascular occlusion or thrombosis, prolongation of circulation time from arm to leg, disappearance of pupillary reflexes, cardiac arrhythmias such as sinus arrhythmia and auricular fibrillation. All Talbot's patients whose temperature reached 80° F. developed fibrillation, which was corrected by digitalis, quinidine, and restoration of body temperature. Unless fluid balance is maintained there is haemoconcentration with an increase (25%) in the red cell count. The white cell count increases several-fold with a rise in the percentage of polymorphonuclear cells. Routine urine analyses for albumin, sugar, and formed elements were negative.

The principal conditions treated up to the time of Talbot's publication were intractable pain, cancer, morphine addiction, leukaemia, and schizophrenia. Relief of pain may well be the most important gain, and all observers are in agreement concerning this; two-thirds of the patients treated had much relief. Some have found that sedatives, narcotics, and operative intervention (chordotomy and rhizotomy) for pain are no longer necessary. Morphine addiction *per se* has responded to general hypothermia, and the use of cold in diminishing the undesirable effects of alcoholic intoxication has been appreciated for at least 150 years. Talbot refers to a gentleman named Weeks who lived about that time back and was a great votary of Bacchus. For fifteen or twenty years he was in the habit of plunging into cold water when he rose from his bottle and of actually going to sleep in a trough full of water with his head

especially supported. Instead of experiencing debility, lassitude, headache, and nausea, he found himself on awaking cheerful, refreshed, and free from all effects of intoxication.

The value of greatly reduced temperatures in other fields of surgery is also being studied by Dr. F. M. Allen of New York and others. Fundamental investigations are being very carefully conducted in order that undue enthusiasm over a spectacular novelty may not be followed by disillusionment, which may obscure any real value of the method. Dr. Allen introduces the use of the tourniquet with low temperature and gives some data of amputations through the thigh and the lower leg for diabetic gangrene and arteriosclerotic gangrene in aged patients; anaesthesia is produced by keeping the bloodless leg tissues for a period of from one to five hours at a temperature of about 5° C. by means of ice-bags or iced water. The leg is rendered bloodless before cooling by careful application of a narrow tourniquet after elevation of the leg to drain off any non-infected blood. The use of cold makes it possible to disregard the rule that a tourniquet must not be applied to a diabetic or arteriosclerotic limb. The tourniquet is released after the operation, when all is in readiness for closure of the wound. It appears that both primary and secondary shock are abolished by suitably low temperature in the damaged tissue, and the surgeon has the opportunity of working in a bloodless and shockless field; the low temperature inhibits growth of bacteria. Loss of vitality in wound flaps or mutilated tissue is also treated by local reduction of temperature, as is post-operative shock. Healing is slowed down but not stopped by low temperature. Attention is also being directed towards the possible use of hypothermia in military surgery and in embolism and other accidents. Embolism of a main artery is one of the conditions in which warming a limb is disastrous, and Dr. Allen believes that a suitable degree of refrigeration may be the most important non-operative treatment. At a temperature of 5° C. the requirements of the tissues for oxygen are reduced, and in intact animals the period of survival of the bloodless limb tissues has been experimentally increased at least to fifty-four hours as against the few hours or minutes at higher temperatures. Dr. Allen has attempted to apply this finding to surgery, but at present his researches are at a preliminary stage.

LEUCODERMA FROM RUBBER GLOVES

Although from time to time cases of dermatitis occur which can be attributed to the wearing of rubber gloves, they are, on the whole, rare considering the nature of the complex substances, organic and inorganic, commonly used in the preparation of rubber. A recent report* by Schwartz and Oliver of an occupational leucoderma, due to an ingredient in the rubber of the gloves they wore, among negro and white workers in tanneries in the U.S.A. is therefore of interest. The report provides a model of how an investigation into

dermatitis should be carried out, and on this ground alone is worth detailed consideration. Workers in tanneries are subject to skin and nail affections due to tannin, sulphides, lime and chrome salts, and also to bacterial infection of the skin, but this leucoderma was something new. The condition was preceded by itching and mild dermatitis in some cases, but there was no great discomfort or disability. Localization of the lesion to the hands quickly led to an investigation of the gloves, which were identified by the manufacturers as "acid-cured" gloves in which the rubber mix had recently been modified by the addition of 0.2% of an anti-oxidant not previously used. This anti-oxidant was the monobenzyl ether of hydroquinone, which, as used, is a tan-coloured light powder with an aromatic odour, a specific gravity of 1.26, and a melting range of 115° to 120°C. It is very slightly soluble in water and benzol and in rubber to 2%; it is said to be non-toxic with ordinary handling, and it does not "bloom" when used up to 1% in rubber. As it does not discolour in daylight and only slightly in direct sunlight, it was recommended for use in white and light-coloured rubber goods. Further, it is not as readily attacked as other anti-oxidants by acid-cure (sulphur monochloride). The incidence of the leucoderma among the Mexicans, negroes, and white Americans wearing these gloves was respectively 31%, 29%, and 21%. In the negroes the areas of depigmented skin were a flat white, but in the white workers the leucoderma showed only in the summer, when the skin of the glove areas failed to tan. In no case were the hairs bleached.

A comprehensive series of patch tests of all the various constituents, including the acid-cured rubber which did not contain the anti-oxidant, the dimethylamine used by one tannery as a de-hairing agent, and the various tanning liquors, were carried out. All the workers reacted to the anti-oxidant patch with greater or less degrees of leucoderma, and only one reacted to a piece of acid-cured rubber containing a mere trace of the anti-oxidant; none of the remaining constituents of the rubber gave leucodermic reactions. The patches were allowed to remain in contact with the skin for seven days; the leucoderma appeared on five of the ten patients tested two weeks after the patches were applied; six months later three more showed leucoderma, and two of the first five were now repigmented. In the majority of cases leucoderma began to develop about a week after the patches were removed. There was skin reaction and leucoderma after only seventy-two hours' application of the anti-oxidant either alone or in unvulcanized or vulcanized rubber. Hydroquinone (1% of which was present in the original anti-oxidant) failed, even in strong concentration, to cause leucoderma. Subjects who had had no previous contact with the anti-oxidant developed leucoderma some months after application of the patches. It would thus appear that this anti-oxidant leads, after a considerable time, to depigmentation of the skin but not of the hairs, and whatever the mechanism may be, the oxidase system responsible for the development of pigment in the skin is not permanently damaged. For repigmentation gradually occurs if there is no further contact with the anti-oxidant.

* *Amer. J. Surg.*, 1941, 52, 225.
* *Publ. Hlth. Rep.*, Wash., 1940, 55, 1111

The histology of the depigmented and repigmented skin was studied, the "dopa" staining method and the usual haematoxylin-eosin technique being used. This showed a fairly sharp line of demarcation between the normal and leucodermic areas of skin, with a gradual decrease in pigment particles in the cells of the basal layer as this was approached. The process of repigmentation could be seen in action by the presence in the basal cells of "dopa" positive particles interspersed among areas of pigment-free cells. No inflammatory reaction in the skin was noted, nor were the pigment cells morphologically affected. The mechanism by which this action of the monobenzyl ether of hydroquinone is brought about is not certain. Schwartz and Oliver consider that anti-oxidants act by their greater affinity for oxygen, thus, for a time at least, inhibiting the action of oxygen on the rubber. The formation of melanin in the skin is a complicated process, but in simple terms it may be described as the oxidation of 3,4 dihydroxyphenylalanine (dopa reagent) to melanin by an oxidizing enzyme in the melanoblasts of the epidermis. Whether the precursor of melanin in the skin is identical with dopa is not clear, but at any rate the two must be closely related. The localization of dopa oxidase, as the enzyme is called, to the melanoblasts is demonstrated by fixing skin sections in formol and treating them for a few hours to a few days with 0.1% dopa buffered to pH 7.3 or 7.4. The cells containing the oxidase will thus be stained deeply with melanin. Before a leuco-derma is produced the existing pigment must disappear and new pigment must be prevented from forming. The former was seen to be the result not of bleaching of the existing pigment but of a slow metabolic removal; the second may be brought about by deflecting oxygen from the substrate, by inactivation of the oxidase, or by preventing the formation of the pigment precursor. It is not clear which of these or what combination of them is the true explanation, but from the fact that the "dopa" reaction was negative in the leucodermic areas it follows that the oxidase system was not operative. On the other hand, the fact that repigmentation was slowly re-established shows that the inhibiting factor (presumably the anti-oxidant) gradually disappeared and allowed the oxidase system to operate normally. It seems, therefore, that the action of the monobenzyl ether of hydroquinone in the skin is similar to its action in rubber—that is, it prevents the oxidation of the unsaturated linkages in the rubber molecule and the oxidation of the pro-pigment (dopa) in the skin.

OBSCURE PULMONARY INFECTIONS

The pitfalls that beset the diagnosis of pulmonary tuberculosis in the absence of bacteriological confirmation have been enumerated by Scadding,¹ and they are rendered prominent at the present time by an unfortunate tendency in the Services to board a man out with the diagnosis of pulmonary tuberculosis solely on the evidence of a radiological opacity. In a recent paper Davidson and Ellman² described five patients all of whom had radiological lesions

in the lungs which pursued a benign course. The authors hold the opinion that these were examples of so-called "benign acute pulmonary tuberculosis," as described by Ornstein, Ulmar, and Dittler,³ though in no instance did the sputum contain tubercle bacilli. Many physicians would probably disagree with this diagnosis in some, at least, of the published examples, but the paper is of value because it directs attention to the difficulty of distinguishing between pulmonary tuberculosis and the various atypical forms of pneumonia. A certain amount of confusion has been caused by the indiscriminate use of the term "pneumonitis" to cover a variety of conditions, but Scadding, in a series of articles, has shown that the common forms of atypical pneumonia can be classified conveniently into four groups. The first is described as benign circumscribed pneumonia,⁴ a transient localized consolidation arising in the course of a catarrhal infection of the respiratory tract. This condition is of frequent occurrence, it produces few symptoms, and is commonly found on routine radiological examination. The second form is chronic suppurative pneumonia,⁵ a condition characterized by prolonged pulmonary consolidation and a tendency to abscess formation; the disease may spread, either directly or by aspiration, and when healing occurs it is accompanied by fibrosis. The sputum is purulent and may be offensive, and the patient shows obvious signs of toxæmia. In the third type—chronic diffuse bronchopneumonia⁶—there is a widespread, patchy consolidation of the lungs with fibrosis, the radiographical picture closely resembling that of chronic fibroid tuberculosis; the patient is gravely ill, dyspnoea is the most prominent symptom, and the disease pursues a prolonged but fatal course. The fourth form Scadding describes as disseminated focal pneumonia,⁷ an acute condition not associated with upper respiratory tract infection in which fever, sweating, cough, and, later, sputum are the principal features. Radiologically there is a mottling similar to that seen in miliary tuberculosis, though less widespread, and both the symptoms and radiological lesions disappear in the course of a few weeks.

The aetiology of these infections remains obscure. The sputum commonly shows a mixed flora with no organism predominating. It is probable that the first three conditions are due to the aspiration of infected material into the terminal parts of the bronchial tree, while the recent work of Weir and Horsfall⁸ suggests that disseminated focal pneumonia is a virus infection. An epidemic of atypical pneumonia in infants, probably due to a virus, has been described recently by Adams.⁹ When faced with the need to distinguish between one of these conditions and pulmonary tuberculosis the physician's lot is not a happy one. On the one hand he is in danger of failing to diagnose an early case of pulmonary tuberculosis, while on the other there is the risk of imprinting the stigma of that disease upon an innocent subject. Every recognized aid to diagnosis should be employed. A strong family history of tuberculosis may be a deciding factor. The sputum should be cultured and injected into a guinea-pig whenever possible, and when none is being expectorated it is often possible to obtain a specimen through the bronchoscope. But every investigation may well prove negative or inconclusive, and the search has to be relinquished until the disease either reveals its nature in its own time or remains a mystery. There is a need for new ways of approach to this problem, and the method of diagnostic lung puncture may deserve a more extensive trial.

TRAFFIC OFFENDERS

Driving a motor vehicle is an act that calls for a sense of social responsibility and for physical fitness to perform it. Many diseases and disabilities are incompatible with safe driving, yet in this country epilepsy is almost the only one, apart from blindness, which is generally recognized as a bar to the driver's seat. Among one hundred traffic offenders referred for medical examination by the Recorder's Court in Detroit, there were fourteen with evident neurological disease, four with well-developed mental disease, and fifty-eight, including four epileptics, with isolated neurological signs; these results were compared with a control group, of whom only twenty-two gave similar findings.¹ The persons observed had been chosen by the judge for medical investigation because of the impression they gave the court when they were in the box; so that the grosser medical conditions at least were presented in far higher proportion than among traffic offenders in general. Though only one-quarter of 1% of all the cases passing through the court were referred, the fact that the sample taken shows nearly 20% of seriously disabling disease proves the desirability of some medical supervision for holders of driving licences. The rising figures for deaths on the road in this country will, we hope, persuade the authorities that action of this kind is necessary. A medical certificate of fitness accompanying each application for a licence should be as obligatory as the passing of a driving test. Such a certificate should, on the analogy of a passport, be signed only by a doctor who has known the candidate for some time, because there are mental conditions of great importance in this respect which may not show themselves at formal clinical examination. There is, for example, addiction to alcohol, of which there were fifteen cases in the Detroit investigation. There are also other forms of irresponsible psychopathy—"sociopathy," as it is sometimes called. A well-planned system would provide for a yearly medical examination. This need not cost the State much because, except in the case of paid drivers, it should be charged to the applicant himself. Failing such a comprehensive measure there should at least be a medical examination of all those convicted of careless or dangerous driving, whether merely of speeding, of intoxication while driving, or of actual manslaughter. There are states of mind other than those characteristic of psychoses which should be a bar to driving but which no routine medical examination could eliminate. There are people who desire power and want to overtake everyone on the road, the aggressive who would like everyone else to get out of their way, the anxiously preoccupied whose attention is only half on the driving, the depressed who contemplate a car accident as a means of suicide, the guilt-ridden whose legs fail when they seek to apply the brakes. Few such are likely to be detected until an accident has happened, if then. On the other hand, it is surprising how comparatively few car accidents occur to psychoneurotics, or even to those who are profoundly depressed constitutionally. It has, however, been shown that even in minor road accidents psychiatric investigation is worth while. Some years ago an investigation was carried out on New York bus drivers who had had more than the average number of accidents. The results showed that they were usually people who, at the time, had domestic or financial cares on their minds. It is impossible for any scheme, however perfect, to eliminate all accidents from such causes. But a good system of licensing should demand not simply an affidavit from the applicant of freedom from disease or disabling defect, but a medical overhaul at least at the time of first application and, say, every five years thereafter,

together with a statutory medical examination if any serious traffic offence is committed. Tests of driving aptitude—a cognate problem—have not so far proved themselves enough to make it worth while to apply them to the ordinary candidate for a licence.

PREVENTION OF DIABETES

Prevention of such a condition as human diabetes must depend upon some degree of certainty as to its causation. What, in fact, do we know of the cause of diabetes in man? In spite of the vast amount of work done on the subject both before and since the discovery of insulin, we know little. The fact that insulin can, and in most cases does, control the condition in greater or less measure means that manufacture in the body has ceased, or that insufficient amounts are available, or that what is produced by the islets is inactive, inactivated, or antagonized. The last possibility must be kept in mind in view of the paucity in many cases of pathological signs in the pancreas. But the success of insulin does not help us to understand why an apparently normal young man suddenly finds that he is losing weight and energy, is always thirsty and hungry, and has to get up at night to micturate. From being a normal, active person he has more or less suddenly become a diabetic. Why? The practitioner, having established the diagnosis in the usual ways, inquires closely into the family history, dietary habits in the matter of carbohydrate, and the rest. Family histories of significance are frequent enough to justify the conclusion that a tendency existed in the patient's forebears; but this is far from saying that the condition is hereditary. Any system of prevention which would involve application to all members of families related more or less closely to groups in which diabetes had occurred would in most cases be a waste of time and effort. A history of excessive consumption of soluble carbohydrate is often obtained, but not often enough for it to be regarded as an essential factor in causation. People with diabetes are met with who have had a lifelong aversion from soluble carbohydrates, and big eaters of sugar remain perfectly free from glycosuria throughout life. A history of high nervous tension is common, but so is a history of phlegmatic temperament. Obesity is not infrequently a precursor of diabetes, which may be of the fulminating type or of the so-called hepatic type. Diabetes is met with in children long before dietary indiscretions are likely to have had any serious effect in exhausting the production of the islets. That diet may have something to do with the onset of the disease was suggested by the fall in incidence which is said to have occurred in Germany during the last war. But diabetes appears among people who have never possessed enough means to do more than live on the borderline of starvation. It must be kept in mind, however, that such people tend to feed largely on carbohydrate foods.

Failing any clear knowledge of the primary cause of human diabetes, Best and his co-workers² propose that children with a family history of diabetes should have their blood sugars determined at frequent intervals, with a view to early diagnosis and treatment. They further suggest that measures should be taken to rest the islet tissue by either dietary means or insulin, or both. It is held that in the early stages of the disease rest of the islet tissue will allow of some recovery of the already affected cells, or that it will at any rate spare those not yet involved. In experimental animals the criterion of functional rest to the islet tissue is taken to be a marked diminution of the insulin content of the pancreas, and it was shown conclusively that starvation, starvation with insulin administration, and

a fat diet with or without insulin all produced such diminution in a high degree. Leaving aside the theoretical soundness of Best's interpretation of his findings, let us consider the fate to which he would sentence thousands of children unfortunate enough to have been born into families in which there had been a case of diabetes or glycosuria. Such children would be brought up with the sugar menace always over their heads, with a diet which would make eating an unpleasant task, with the hospital or doctor constantly on their track, and, as they grew up, with rebellion and resentment in their hearts. But such rebellion would be of little avail, for no one could be certain that the inborn tendency to diabetes would not manifest itself at any time if the regime were discontinued. It might even be argued that life as a diabetic would be preferable in that at least the patient would know where he stood and could get a square meal when he wanted it. Further, as pointed out by Lawrence, a diet low in carbohydrate and protein, combined with systematic dosage of insulin, would give the "potential diabetic" all the apprehensions of the unstabilized diabetic about his next attack of hypoglycaemia. The prevention of diabetes must surely lie in the social, physical, and mental improvement of man, and in the re-ordering of his activities. Spontaneous diabetes in animals, at least in laboratory animals, is a rare phenomenon. The relation of carbohydrate metabolism and the function of the islets to brain centres and the pituitary gland is established. Is it too much to suppose that this disease is in some fundamental way one of the prices which man is paying for his departure from the most elementary principles of his constitution? Cases of acute diabetes occur as the result of violent emotional crises or fear. Harassed and torn by wars and horrors, mankind has denied itself or been denied the possible compensation afforded by a healthful life in the periods between conflicts. In peace his anxieties are often scarcely less disturbing. These anxieties on different planes affect all classes, rich and poor. It is at least plausible to associate the high incidence of diabetes among Jews with the many centuries of persecution to which they have been subjected, and the maintenance of the high incidence in regions where persecution has not been practised for some generations to the inherited nervous instability which resulted.

THE TEACHING OF MOTHERCRAFT

For several years the National Association of Maternity and Child Welfare Centres and for the Prevention of Infant Mortality has been concerned with the organized teaching of mothercraft on a national basis. At a recent discussion of the Maternity and Child Welfare Group of the Society of Medical Officers of Health the subject was fully ventilated by Dr. Leslie Housden¹ and Dr. Agnes Nicoll.² They clearly brought out that workers in maternity and child welfare centres are hampered by coming into contact with the mothers too late, when wrong habits have already been formed because of ignorance of even the most elementary principles of child hygiene. The problem has three main difficulties: first, at what stage of the school curriculum should mothercraft be introduced? This is relatively easy to answer, for obviously the last two years of elementary school life must be the time of choice until secondary schooling is universal. (The National Association, mentioned above, issues a syllabus of theoretical and practical instruction for girls under 16.) More difficult is the question of who is to do the teaching. Clearly a married schoolmistress with a family of her own and herself educated by a special course of training for the purpose

would be ideal. But local education authorities, at all events in times of peace, have a habit of dismissing married teachers, so the speakers at the discussion favoured the choice of a health visitor accustomed to teaching. The choice will have to be made most carefully: the type of instruction for schoolgirls needs, for example, to be different from that for young mothers at an ante-natal clinic. There is also the inevitable question of finance, for the teachers must be paid, and it is necessary to have a certain amount of apparatus, charts, and so forth. Here Dr. Housden was on certain ground when he stated dogmatically that the more a mother knows about the care of her children the less they will cost the State. A reduced expenditure on children's hospitals, juvenile courts, approved schools, and even prisons would eventually result from a national policy of educating all girls for home-making and mothercraft. Many girls now leave school with a good grounding in needlework and cooking and perhaps with some instruction in housecraft, but the care of children is sadly neglected. School is the only place where every potential mother of the future can be reached, and the teaching of mothercraft as an essential part of the school curriculum is a practical contribution to the health of the nation. Incidentally the Maternity and Child Welfare Group of the Society of Medical Officers of Health must be congratulated on turning their attention to the future at a time when wartime duties and temporary arrangements might well have absorbed their energy.

LONDON HOSPITAL ENTERS ITS THIRD CENTURY

This year the London Hospital enters its third century. It was in 1741 that, after a meeting held in a City tavern towards the end of the previous year, when it was decided to rent a house in Featherstone Street, patients were admitted, a banking account opened, a house committee elected, and a woman engaged to act as nurse (at a salary of £14 per annum). A chaplain was also appointed in 1741, and held office for nearly fifty years, and in 1741 the first medical student was entered—a Mr. Godfrey Webb, pupil to the first surgeon, Mr. John Harrison. After being in the hospital six months Webb succeeded in obtaining the post of apothecary, and the polite letter he wrote in that connexion, a masterpiece of flourishes, has just been discovered. To-day the London Hospital is the largest in the Metropolis (though not in Great Britain), with a roof space of ten acres, a total area equal to twice that of Trafalgar Square, and normally bed accommodation for 900. Under war conditions the building in Whitechapel maintains only 360 beds, of which 160 are reserved for air-raid casualties, but it has an annexe at Brentwood with 252 beds, which will eventually be increased to 360 when the nurses' accommodation is completed. Since the air raids started the London Hospital has received direct hits—some of them on the first "blitz" night—it has had many incendiaries, and has lost 3,500 windows. But except for the temporary stoppage of such services as lighting and power, it has never been put out of action. Damage has been done to the nurses' homes, the laundry, and the out-patient department, but not to the wards. They tell at the "London" the same story as is told at all the other hospitals—of the conspicuous devotion of the staff, medical, nursing, and administrative.

A special meeting of Representatives of Home Divisions of the British Medical Association will be held at B.M.A. House, Tavistock Square, W.C., on Thursday, September 11, at 12 noon, and will continue on the following day. The Executive Committee will meet at 10 a.m. and the Council at 11 a.m. on September 11.

SYSTEMIC FACTORS INFLUENCING WOUND HEALING

BY

W. GRANT WAUGH, M.D., F.R.C.S.

Surgeons who were actively engaged in the treatment of the wounded in the war of 1914-18 may legitimately inquire how far and in what manner advance in the treatment of wounds has been made. It would appear that progress has been chiefly in the direction of the inhibition or reduction of infection by the universal recognition of the virtue of early incision, appropriate secondary suture, immobilization by closed-plaster or other technique, and the employment of a chemotherapeutic agent. Given the essential factor of the arrival of the patient at a surgical centre within the "contamination period" it may reasonably be expected that septic infection will be avoided in most cases. Unfortunately a time-lag in evacuation is sometimes inevitable, and established suppuration follows. Advance in the treatment of this condition seems to be almost imperceptible: neither local nor systemic employment of the newer chemotherapeutic substances seems of value. Still more disappointing is the relative ineffectiveness of the Winnett Orr technique as compared with its use in the suppurations of civil surgical practice. This may be due to rapid wasting of the tissues in high-explosive wounds which suppurate, with consequent failure of immobilization, recrudescence of infection, and further spread of sepsis. I suggest that the questions of tissue reactions to suppuration and the mechanisms of repair have not received enough attention in this country, and the discussion of some of these, with clinical inferences to be drawn from them, may be useful.

Exact knowledge of the physiological mechanisms of tissue repair now available originates from the systematic experiments in tissue culture of Carrel and his co-workers: the investigation of the biochemistry of local factors which may accelerate repair or by which differential inhibition of regenerating tissues may be effected is due to a number of research workers, among whom Hammett and Medawar may be cited. An excellent résumé of the subject by Riley (1940) deals exhaustively with this aspect of healing. My aim in this paper is to focus the attention of clinicians on the advances in our knowledge of certain systemic or constitutional factors which also have considerable influence on the repair process. These, too, have been the subject of intensive investigation in the United States and to some extent on the Continent, and the information gained from these researches has been translated into clinical practice in those countries (Whipple, 1940).

It is of the first importance that treatment should have a sound physiological as opposed to an empiric background. Two factors of supreme clinical importance may be considered: (1) the influence of vitamin content; and (2) the effect of controlled electrolyte and protein fluid balance.

Vitamin Content and Avitaminosis

High claims regarding a particular influence in repair have been made for the various vitamins, whether applied locally or given in the diet. Many of these are based on faulty premises or imperfect observation, and it may be stated categorically: (a) that no locally applied vitamin has been shown to influence tissue growth, whether the results are assessed scientifically by mensuration or by the effect on mitosis and cell proliferation as estimated either by photomicrography or by measurement of the nucleophosphorus

output; and (b) that only vitamins C and K taken in the diet have been shown to exert a direct effect on the mechanisms of repair: deficiency of vitamin C results in a fibroblastic aplasia, affecting the collagenation of the proliferated fibroblast cells and their maturation to formed fibrous tissue, and causing weak irregular scars; in vitamin K deficiency the production of prothrombin is inhibited, capillary clotting retarded, and the rhythm of vascular regeneration interrupted.

Several clinical inferences may be drawn from these facts. First, at the risk of appearing polemical, I would say that there is no scientific basis for the very popular use of cod-liver-oil or ointment dressings for the supposed virtue of their vitamin content. I regard their use as an example of pseudo-scientific mumbo-jumbo: any healing effect they may possess dwells, I believe, in their mechanically atraumatic character, and perhaps in the fact that a few hours after their application the wound surface will furnish a distinctly acid reaction (a large volume of research indicates clearly that the discharges of the healing wound have a consistently high hydrogen-ion content). Careful planimetric measurement in six cases treated by cod-liver-oil dressings showed no acceleration of healing, as plotted by the du Noy formula.

Secondly, it is obvious that the diet of the patient in the surgical ward should contain foods of a high vitamin C content—e.g., fruit and green vegetables—and that care should be taken to ensure that the vitamin is not destroyed in cooking. The recovering patient should have a daily intake equivalent to 75 to 100 mg. of ascorbic acid. If this cannot be obtained from the diet it should be given in tablet form. The effect in the case which is slow to granulate is sometimes dramatic; but no effect on epithelization is to be expected. Thirdly, vitamin K is now available commercially, but by reason of expense its use should be reserved for cases in which recurrent bleeding from granulation tissue is encountered or minor secondary haemorrhage occurs.

Electrolyte Fluid and Protein Balance

This complex factor may be studied from two angles: (a) protein loss and protein replacement, and (b) the fluid balance and the occurrence of oedema.

HIGH PROTEIN INTAKE

Experimentally, observations of the measurement of healing wounds (Carrel, Fischer) confirmed by those on the tensile strength of wounds (Howes, Ellis, Cutler) have established the fact that a latent period of about four days before repair begins is constant for all clean wounds; this delay is reduced or eliminated by instituting a high protein diet from the start: high fat (ketogenic) diet, on the other hand, prolongs the lag period. Cuthbertson (1936) showed that the protein loss following fracture was very high, and the same is true in cases of prolonged suppuration. I made repeated estimations of the urea excreted in ten cases of prolonged bone or joint suppuration in my wards; this averaged 46 grammes daily: as the excretion of urinary chloride was not equally raised it may be assumed that the increased urea output is due to tissue destruction. In a case reported the nitrogen loss was 26 grammes daily—equal to nearly 2 lb. of muscle tissue.

The clinical significance of the hydrogen-ion content of wounds has received little attention in British surgery. From the work of Girgola (1924), Rohde (1926), and others it may be regarded as certain that the healing wound is acid in reaction, and that such acid tissues offer a resistance to invasion by organisms which diminishes as the pH

approaches the neutral or alkaline zones. An acid diet maintains this wound acidity, and may contribute to recovery in this way also.

Protein deficiency retards repair in another way. That the most powerful enemy of repair is the occurrence of oedema is a clinical fact with which we are all acquainted; it is well illustrated by cases of delayed union of fractures in which tissue support has been inadequate or gravitational oedema has been permitted. The protein molecule is of large size, and in hypoproteinaemia the missing large molecule is replaced by the smaller molecules of inorganic salts, especially the chlorides, and as a result salt action occurs in the tissues, followed by intercellular oedema.

From these physiological researches the important clinical lesson may be drawn that high protein intake should be arranged for at the earliest day after injury or operation and should be maintained during the whole course of healing. There is a persistent tendency to put a patient on light—that is, carbohydrate—diet in the early days, especially if the temperature is elevated. It will be seen that this is wrong: provided the digestion is competent the diet should include milk, grated cheese, egg albumen, and perhaps gelatin, followed by pounded fish, scraped meat, etc.; while fats, including butter, should be materially restricted. Protein-containing vegetables and cereals—e.g., peas and beans, oatmeal, and bran—may be useful as substitutes in the present shortage of animal proteins. Although cheese has a high fat content it is retained for the ready absorbability of its protein. For parenteral introduction blood plasma no doubt is the ideal, but the supply is limited; a solution containing the total amino-acids of casein, together with dextrose, is being employed in the United States, and the results so far are very hopeful. It is possible that a similar solution may become obtainable in this country.

LOCAL ELECTROLYTE FLUID BALANCE

It has been indicated that massive oedema is greatly inimical to repair: this is equally true of its occurrence locally. The importance of preventing it by maintaining adequate tissue support, by obviating gravitational fluid collections, and by maintaining functional movement so far as possible cannot be overstressed; for similar reasons care should be taken that tension sutures are not drawn so tight as to create areas of oedema between them. In addition some standard should be adopted for the administration of fluid: too often indiscriminate injection of dextrose-saline solution merely results in wrecking the fluid balance, sometimes to the extent of establishing a condition analogous to anasarca. Intake should bear relation to excretion and an endeavour be made to estimate the excretion of fluid as urine in each case where saline infusion is being resorted to. A good working rule is that no more than one and a half times the amount of fluid excreted as urine in twenty-four hours should be administered. Owing to rapid surface evaporation cases of burns can tolerate rather more, but even these wounds can be drowned in tissue dropsy.

These adjustments in the treatment of cases of wound suppuration have been in use for several months in cases under my care, and it is certain that improvement in the condition of these patients has resulted, as indicated by arrest of wasting, absence of oedema, acceleration of healing, and the maintenance of a normal blood pressure. I believe they form a distinct advance in our technique. It is difficult to ascertain the body weight of bed patients. In three cases, however, it was taken weekly; in these an average loss of 24 oz. a week was arrested on the institution of the acid diet, while a fortnight later the average gain was 30 oz.

Wartime High Protein Diet

Adequate supplies of carbohydrate are readily obtained, but the difficulty of maintaining a high protein diet under war conditions is patent. I must here express my indebtedness to Miss Gatenby, matron of the Memorial Hospital, Darlington, for her effort and ingenuity in this matter: at my request she has added the following notes.

In June, 1939, the full diet given in orthopaedic cases and wound infections possessed a moderately high protein content—approximately 110 to 120 grammes of protein a day. A cooked breakfast was supplied from the hospital kitchen to all patients (previously only tea and bread-and-butter were provided), and a better-balanced diet was maintained. The average daily diet was as follows—with as much variety and as little repetition as possible:

- 6 a.m.: Tea and milk, bread-and-butter (6.2 gm.).
- 8 a.m.: Milk 2 oz., oatmeal porridge 2 oz., kipper 3 oz., tea and milk, bread-and-butter (31 gm.).
- 12 noon: Rabbit stew 4 oz., potatoes 8 oz., chocolate pudding 4 oz., custard 4 oz. (42 gm.).
- 3.30 p.m.: Tea and milk, bread-and-butter, 1 egg (provided by patient) (16.5 gm.).
- 6.30 p.m.: Vegetable soup 8 oz., bread-and-butter, cocoa (15 gm.).
- 10 a.m. and 10 p.m.: 5 oz. milk, cocoa, etc. (10.9 gm.).

This diet yielded 121.6 grammes of protein and gave 3,047 calories.

In August, 1940, an endeavour was made to raise the protein content of the full diet to approximately 145 grammes daily, and emphasis was laid on the importance of persevering with a higher protein intake during the first few days until the patient was in a fit condition to partake of the fuller and more substantial forms of diet. The suggested daily diet for the first week was: 1 egg, 5 oz. milk (10.4 gm.), egg custard (5.9 gm.) (1 egg = 5 oz. of milk), 4 oz. minced chicken (29.6 gm.), 6 oz. pounded fish (37.8 gm.), milk jelly (8 gm.), extra milk fluids 5 oz. (4.5 gm.). Total, 96.2 grammes of protein. Balcony treatment, whenever possible, greatly improved the patients' general condition, appetite, and outlook.

To obtain 145 grammes of protein daily the following diet was given:

1. *Animal Protein*.—Breakfast: 4 oz. herring (21.6 gm.), 2 oz. milk (2 gm.), tea (milk) (1.8 gm.). Dinner: 4 oz. roast beef (30.4 gm.). Tea: 1 egg (5.9 gm.), tea (milk) (1.8 gm.). Supper: 2 oz. cheese (14.2 gm.). 10 a.m. and 10 p.m.: 5 oz. milk, cocoa, etc. (10.9 gm.). Approximately 88.6 grammes of protein.
2. *Vegetable Protein*.—Breakfast: 2 oz. oatmeal (7.6 gm.), 8 oz. bread-and-butter (8.8 gm.). Dinner: 4 oz. dried peas (8 gm.), 3 oz. jam tart (3 gm.), 8 oz. milk pudding (10.4 gm.). Tea: 4 oz. bread-and-butter (4.4 gm.). Supper: Vegetable soup (4.8 gm.), cocoa (5.8 gm.), bread-and-butter (4.4 gm.). Approximately 57.2 grammes of protein.

The pulses are among the cheaper foods, and in large quantity will raise the amount of vegetable protein, circumventing the deficiency of animal protein.

The following are valuable foods: Dried peas, butter beans, haricot beans, lentils: can be given as a vegetable or added to soup stock. Pea and bean flour: 1 heaped teaspoonful in each plateful of soup has a protein value equivalent to 1 oz. of meat; by making soup with milk the amount of protein is trebled. Macaroni, semolina, barley: Can be used as milk puddings or for thickening soups. Stet puddings, with milk or egg custard. Cheese: protein and fat content are nearly equal, and both are high. (It is possible to obtain a certain amount of cheese, and necessitous patients benefit.) Corned beef: high protein value, used as iron rations. Farex: added to milk puddings and porridge. Hovis bread: 3 lb. bread yields 100 grammes of protein (richest in nourishment of all breads). Peanuts: 1 oz. yields 8.5 grammes of protein. Bovril and oxo, made with milk: 1 teaspoonful of bovril equals 1/5 oz. meat.

Alternatives for Breakfast.—4 oz. fish cakes (13 gm.), 4 oz. sausage, 2 oz. sardines (11.6 gm.), 2 oz. bacon (13.8 gm.), 3 oz. haddock (18 gm.), 3 oz. herring (16.2 gm.), 3 oz. scrambled eggs (8.7 gm.).

Alternatives for Dinner.—2 oz. boiled mutton (14.6 gm.), 2 oz. fried liver (16.6 gm.), 2 oz. stewed beef (17.4 gm.), 4 oz. stewed tripe (20.4 gm.), 4 oz. fried cod (2.6 gm.).

NEED FOR BIOLOGY IN EDUCATION

SIR WALTER LANGDON-BROWN'S ADDRESS

At the annual meeting of the British Social Hygiene Council, held at B.M.A. House on July 31, Sir WALTER LANGDON-BROWN delivered an address on "Biology and Health." He began with some remarks on the blight which has fallen upon European culture, the hapless conditions of university life on the Continent, and the subservience of scientific work to National Socialism. Incidentally he mentioned that the *Münchener Medizinische Wochenschrift*, formerly one of the leading medical journals of the world, had now become scientifically negligible, the happy hunting-ground of naturopaths and other cranks who hoped to catch the Fuehrer's eye. The fate of *Pflügers Archiv*, which was for more than seventy years the leading publication of physiological and biological research, was also significant. In 1932, the last pre-Hitlerian year, it ran to five volumes; in 1938 it appeared as one slim volume, the articles being mainly written by Russians and Japanese.

Sir Walter Langdon-Brown went on to say that, brought up as he had been, he found it hard to disbelieve in progress, though not necessarily as a law. Moreover, he thought the study of biology did impress the idea on the mind as the increasing complexity and adaptations of animal life came to be studied. If the study of biology had been pursued with the same intensity as that of chemistry and physics, it was possible that men might have become so interested in the wonderful processes of life that they would not be so keen on inflicting death. Here he mentioned the three main planks in the platform of the British Social Hygiene Council: (1) the study of biology as a subject of general education; (2) the education of the educator; and (3) general enlightenment on the principles of social hygiene. The general public would have no adequate grasp of the principles of social hygiene until they had some idea of biological principles. Recently an inspector of a certain examination of older students remarked to him on the relatively high percentage of failures in biology and the relatively low percentage of failures in physics and chemistry. Inquiry revealed that the teachers in many of the various institutions preparing the students had not been interested in biology and regarded it as a tiresome sideline of their work. If a teacher could not make biology interesting he should not teach at all. Perhaps it was the romanticizing tendency of the English which had made them unwilling in the past to face the uncomfortable fact that behind the divine mystery of the continuity of life lurked the shadows that were responsible for venereal diseases; but it was ignorance of biology rather than unwillingness to face facts which was responsible for failure to realize the natural law that whenever the continuity of life was threatened the impulse to create more life was increased.

Bearing in mind the shadow which accompanied this natural impulse, the work of the British Social Hygiene Council assumed a new significance. It was beside the point to say that there had been no sensational rise in venereal diseases in this war as in the last. It was like saying that the stirrup-pump had served so well when the last shower of incendiaries fell that it could now be discarded. In view of the fact that it was sometimes said that medical officers of health had little opinion of the usefulness of the work of the Council, fifty leading medical officers had been circularized, and the first thirty-three who had replied all said that they thought the Council served a useful purpose, though reservations were made by two. All replied in the affirmative on the question whether direct education on venereal disease was still necessary, and all except four (who were doubtful) were also in favour of a more general type of health education.

The Untrained Intruder

In view of the recent debate in the House of Commons on the Pharmacy and Medicines Bill, Sir Walter Langdon-Brown added a few remarks on the need for educating legislators. He said he was impressed by the curious bias shown in favour of the intruder into a sphere for which he was not trained, even though he was trained for some other. For example, the pharmaceutical chemist was to be safeguarded if he wished to take over the doctor's work of advising and prescribing, but when it came to his legitimate business for which he had been highly trained, sympathy was shown to the competing interests of the co-operative stores, the grocer, and the herbalist. The Minister of Health was very tender towards herbalists, pointing out that an expert committee had recommended that the collection of herbs for medicines and drugs should be encouraged as much as possible. But as he himself read the report of that committee, what it had in mind was the collection of herbs, not for their administration in a crude form, but to enable the extraction of their active principles in a pure state by skilled pharmacological chemists. The *Pharmacopoeia* would indeed be denuded if deprived of pure drugs of vegetable origin. In other words, the pharmacologist carried out the work of the herbalist in a much more scientific form to a higher pitch of accuracy. What struck him about the whole tone of that debate was the extraordinary naïveté with which the value of evidence in these matters was assessed. It might be said that ultimately some steps were taken in the right direction, but these would have been firmer and more speedy if the majority of the legislators had had a modicum of science imparted to them in their general education. There would not then have been so many who seemed willing to believe that an untrained man might intuitively discover a cure for a hitherto incurable disease which could only be brought to the notice of sufferers by advertisements in the lay press.

AWARD FOR GALLANTRY IN CIVIL DEFENCE

The award of the M.B.E. (Civil Division) to Dr. WILLIAM REMINGTON, medical officer, Mobile First Aid Unit, A.R.P. Casualty Service, Woolwich, is announced in a *Supplement to the London Gazette* dated August 1. The announcement reads as follows:

"During enemy air raids Dr. Remington has shown resource and a high sense of duty. A high-explosive bomb demolished dwelling houses. Dr. Remington was lowered through a hole in the top of the wreckage, which was in a very dangerous condition, to some casualties underneath. He gave them morphine and remained while the rescue party dug out the victims. On another occasion when a building was demolished and people were trapped, Dr. Remington, regardless of his own safety, stayed at the incident for three hours giving treatment to the casualties."

Walter Bauer and Joseph C. Aub (*J. clin. Invest.*, 1941, 20, 295) state that patients with acromegaly have an abnormal calcium and phosphorus metabolism, characterized by an increased urinary secretion of these minerals. In one patient x-ray treatment of the pituitary caused a reduction in urinary excretion of calcium and phosphorus, in the metabolism of which, the authors conclude, the pituitary gland must be considered one of the controlling factors.

LUNG INJURIES IN AIR RAIDS

A DISCUSSION ON PATHOLOGY AND DIAGNOSIS

A conference on the pathology and diagnosis of lung injuries in air raids was recently held at which a number of expert observers pooled their views on this important subject. A full report is printed below.

Sir JOSEPH BARCROFT, who was in the chair, began by saying that a town might be attacked in a number of different ways at the same time. A mixed bag of casualties might occur—some from gas (more perhaps than they guessed), some from blast, and so on. The question was, in relation to the lung, how to sort out the casualties in accordance with the various causes of injury.

Action of War Gases on Lung

Prof. G. R. CAMERON divided gases into those absorbed through the lungs with little local effects and those which acted wholly or mainly on the lungs, producing bronchial damage and bronchopneumonia or alveolar damage and acute pulmonary oedema. Arsine was an example of the first group: particulates, chlorine, hydrogen selenide, phosgene, nitrous fumes, mustard gas, and lewisite vapour belonged to the second group. Bronchial damage resulted in bronchial spasm and destruction of bronchial epithelium. It might be caused either (1) by the irritant gas acting on the lining epithelium with liberation of histamine-like substances, or (2) through irritation of nerve-endings. Mucous glands were stimulated, often with free outpouring of mucus, which tended to plug the bronchial cavities and cause collapse. Bronchopneumonia might follow such blockage when infection occurred.

Four views had been held concerning pulmonary oedema: (1) The gas might act directly on the alveolar capillaries, altering their permeability so that plasma exuded out into the air spaces. (2) The gas might liberate H substances from damaged lining alveolar cells. (3) Oedema might be secondary to cardiac failure. (4) Lung lymphatics might become blocked, with lymph stasis and overflow into the alveoli. Some gases acted on the capillaries—for example, lewisite and mustard. Although there was little histological evidence that phosgene altered the permeability of capillaries, there was every reason to believe this to be the case. The second view was debatable, as there was much uncertainty as to the nature of the alveolar lining. Cardiac failure was most often secondary to oedema and not the direct cause. No information existed about lymphatic blockage; indeed, the function of lymphatics in the lung was obscure. Certain risks arose from these lung changes. Bronchial spasm resulting from high concentrations of gas might lead to acute asphyxia and interstitial emphysema. Bronchial destruction was more important because of the danger of bronchopneumonia or bronchiectasis, but fortunately these complications were not common. Pulmonary oedema, if acute, might lead to cyanosis and death from asphyxia. If not so acute there were incapacitation and liability to cardiac failure or infection of the lungs. Haemoconcentration might also add considerably to the risks of circulatory failure. In the dog exposed to phosgene haemoconcentration was high, but quickly passed off. Nevertheless the oedema persisted and the animal might die days after from pure pulmonary oedema. In rabbits haemoconcentration was rarely seen with phosgene, though oedema was marked. What, therefore, was the significance of haemoconcentration? What significance, too, was to be attached to mild pulmonary oedema? How quickly was oedema fluid absorbed from lungs? How much oedema was necessary to produce incapacitation of the patient? These questions, Prof. Cameron said, which were of great practical importance, still remained to be answered.

Lung Injuries in Air Raids

Prof. G. HADFIELD confined his remarks to air-raid casualties presenting severe respiratory symptoms without obvious surgical injury. Such cases included: (1) those suffering from "pulmonary concussion" without damage to the thoracic cage; (2) those suffering from asphyxia; and (3) those whose symptoms were the result of pulmonary fat embolism. Pulmonary con-

cussion, he said, was characterized by multiple pulmonary haemorrhages of considerable size throughout both lungs, usually deep in the lung substance but with no constant relation to the ribs or ramifications of the bronchial tree. Rib markings could be identified only in lungs from infants or young children, suggesting that the elasticity of the thorax predisposed to their production. Naked-eye laceration of the lung or irregular tracking of blood through the lung substance was exceptional, and often no blood was present in the pleural cavities. The size of the haemorrhage was clearly related to the survival period, reaching a maximum in about four hours. In cases surviving for thirty-six to forty-eight hours haemorrhagic areas were, on the whole, no larger than in those surviving four to eight hours only. Capillary bleeding seemed to be responsible for the haemorrhage. A fibrin network formed in the alveoli, and a mononuclear cell exudate appeared, so that in thirty-six to forty-eight hours the histological picture was strikingly reminiscent of lobar pneumonia in the red hepatization stage ("pseudo-pneumonia"). Asphyxia might be presumed to have been a major cause of death when the air passages were found to be obstructed by powdered plaster, brick-dust, etc. It might also be the cause of death when the thorax had been compressed by a heavy mass of wood, stone, or metal. Inhalational asphyxial lungs frequently showed haemorrhages; other cases showed collapse and oedema, which were frequently much more extensive in one lung than in the other, with the usual post-mortem signs of asphyxia. Carbon monoxide poisoning, probably the result of bursting of gas mains, was a frequent complication of pulmonary concussion and asphyxia. The proportion of cases in which fat embolism could be deemed to have caused death was uncertain. Small quantities of fat in the pulmonary capillaries were found in a high percentage of deaths from trauma of any kind. Only when the quantity of fat was large and there was embolism of the glomerular capillaries could much importance be attached to this condition. There was usually a latent period between the incident and the development of dyspnoea. A gross traumatic lesion of subcutaneous fat with a collection of autolysing fat and blood clot was usually found post mortem.

Prof. Hadfield then outlined the clinical manifestations of pulmonary concussion, and emphasized the rapid development of shock, with frequent thready pulse and extreme expiratory dyspnoea. Severe pain and great tenderness of the trunk rapidly developed in the worst cases—probably the result of intramuscular haemorrhage. Dyspnoea might be due to haemorrhage into the respiratory muscle. Restlessness, which was prominent, might be the result of subarachnoid bleeding. Haemoptysis was common within an hour or so of the incident, and tended to be repeated. Dyspnoea became much worse in patients dying after thirty-six to forty-eight hours, and there was haemoconcentration with rise in venous blood pressure. A large venesection might relieve these features. Prof. Hadfield also emphasized the progressive nature of the haemorrhages in pulmonary concussion, and pointed out that one of the chief principles of treatment must be to immobilize the patient as soon as possible and to disturb him as little as possible for a period of several days.

Sir JOSEPH BARCROFT asked how far blast effects were due to something which "hit you outside or inside your lung." It had been shown, he thought, that in a window which had been broken by blast the glass fell out and not in. Was it possible that the burst of the capillary walls was outwards?

Pulmonary Oedema in Gas Poisoning

Prof. SHAW DUNN stressed the importance of dosage of gas in the evolution of symptoms. High concentrations of phosgene elicited violent respiratory disturbance with oedema and overdistension of the lungs, terminating fatally in a few hours; lower concentrations caused early dyspnoea and steadily progressive oedema, which might be fatal but was susceptible to treatment by venesection and oxygen administration. Bronchial spasm was an early event and contributed to the sensation of tightness in the chest and difficulty of drawing breath. Bronchopneumonia was a serious though later addition, and might occur more readily in man than in animals owing to auto-infection or to droplet infection in wards. It added considerably to the risk of fatality, and also, where recovery took place, to the likelihood of permanent damage to the lungs.

Pulmonary oedema was the most fundamental problem in poisoning by lung irritants. Capillaries in the juxta-bronchiolar alveoli showed dilatation and engorgement, with thrombosis in some, and oedema fluid came from those capillaries through which blood continued to flow. The higher the dosage of gas the greater were the dilatation and engorgement of capillaries, and cardio-respiratory embarrassment was more severe, though oedema was less in bulk. Prof. Shaw Dunn discussed the importance of altered capillary permeability in the production of pulmonary oedema, and raised several interesting points. (1) The amount of damage, though sufficient to determine abnormal escape of fluid for many hours, was yet so limited in degree as to permit continued blood flow. (2) There was no evidence that permanent structural changes occurred in the alveolar walls. (3) The most prominent histological evidence of capillary damage was dilatation and congestion. (4) At any moment the total pulmonary blood flow was being transmitted through only a proportion of the capillaries and not through the whole network. Pulmonary capillaries in the gas lesion might thus be visualized as having (a) a slower blood flow; (b) an increased blood content applied to a greatly increased filtering surface; (c) a higher lateral blood pressure, since capillary diameter was enlarged; and (d) walls thinner than normally, due to the distension. These factors appeared adequate to account for the leakage of fluid from the capillaries. Escape of this plasma fluid into the air spaces was contributory to haemoconcentration, and the increased viscosity of the blood which resulted doubtless accounted for embarrassment of the pulmonary circulation. Another contributory factor was the greater pressure exerted on pulmonary capillaries by the fluid in the alveoli than by air. Well-timed venesection, which was so valuable in the treatment of blue cyanosis in gassing, depended not only on alleviation of cardiac embarrassment by removal of blood from an overloaded venous system, but also on the reduction of blood volume, which would favour return of fluid to the circulating blood, even from the lungs. In the stage of grey cyanosis, however, peripheral circulatory collapse had set in and venesection was unlikely to be helpful.

Prof. Shaw Dunn thought it unlikely that confusion would arise between the initial concussed state of blast patients and any stage of gas poisoning. He agreed that the clinical conditions would become much more complex if the effects of poisonous gases were added to those of ordinary trauma, as might easily be the case in air attacks.

DIAGRAM OF MAIN TYPES OF HAEMORRHAGIC CONCUSSION OF LUNGS

The primary lesions are shown on the right: (1) Phrenico-costal sinus contusion with related liver damage. (2) Two "rib markings" are shown in the upper lobe; these extend to a variable depth and tend to become confluent posteriorly, where they may merge into (3) massive hilar contusions (3'). The hilar lesion is most massive posteriorly. The secondary lesion (3') is shown in the left lung—innumerable haemorrhagic spots, due to inhaled blood, varying in size from about a pin's head to that of a silver threepence. Their distribution is fairly uniform over one lobe, one lung, or both lungs. The variations evidently depend on the amount of blood entering the bronchi and the posture of the patient while the blood is in the bronchi.

Types of Haemorrhagic Concussion

Dr. G. R. OSBORN outlined his experience of primary, secondary, and reactionary lung lesions resulting from a bomb explosion. Primary features were: (1) rib markings, best seen in infants, ill defined in adults, single or multiple, with a location suggesting that they were inflicted with the lungs in the inspiratory position; (2) phrenico-costal sinus contusion; (3) massive hilar contusion. The last, if of obscure origin, might possibly be explained by the penny experiment (if a penny was knocked against a row of pennies only the end one flew off). With a large compressing force the alveoli with air locked in behaved as pennies, and the force was transmitted to the deep parts of the lung in the region of the hilus. In the larger primary lesions the alveoli were packed with red corpuscles which without doubt came from the alveolar capillaries, although the latter were so compressed that the holes through which they had escaped could not be seen. Inhalation of blood was a secondary lesion and resulted in scattering of blood throughout the lungs as small red spots. Reactionary lesions were principally acute pulmonary oedema, "pseudo-pneumonia," and true pneumonitis. Oedema might come on and prove fatal within an hour, or it might not occur for several days. Dr. Osborn thought that cases of acute pulmonary oedema fell into three groups: (1) those primarily due to brain lesions, (2) those due to left ventricular failure, and (3) those due to pulmonary causes. Left ventricular failure was not a satisfactory explanation for all cases. He described a case of lung oedema in a man of 29 with rupture of an aneurysm of the middle cerebral artery. The thoracic organs were normal, and there had been no injury. It was often possible to detect a nervous factor in cases which were apparently due to left ventricular failure or pulmonary lesions. Morphine was the only drug likely to have an effect on the condition.

A Case of Phosgene Poisoning

Commander FAIRLEY described an unusual case of human phosgene poisoning. The patient was an Oxford student who was one of a party round which a tube of phosgene was passed at a demonstration. She was the first person to smell the phosgene. A capillary tube of phosgene was simply cracked in a glass bottle, and she then took a good sniff at the bottle and at once coughed. She had no immediate symptoms, but later in the day began to cough and had all the symptoms of acute asthma. It was not known what was the actual dose of phosgene inhaled. She then became acutely ill, breathing very rapidly, making wheezing noises, but showing no cyanosis. She was so ill that she had to be taken to a nursing home, where she was given continuous oxygen for a week. It was possible that there was a neurotic element in her case. Commander Fairley said he had carried out some experiments on goats in order to try to imitate the conditions under which the patient had inhaled phosgene. The goats were fitted with rubber respirators which were connected to bottles in which similar capillary tubes of phosgene were broken. Phosgene could be smelt in the air expired by the goats. Symptoms similar to those found in the girl were produced. The goats began to breathe very quickly and were obviously ill and restless. Blood counts revealed no change. The goats were killed later, and at necropsy showed no pulmonary oedema, except a very slight degree in one goat. The experiment was repeated, but the phosgene was first put in a Douglas bag, so that the dilution was much greater. This caused no symptoms. The capsules contained 30 mg. of phosgene, which would liberate 8 c.cm. of gas. This was theoretically a fatal dose, but they did not know whether the girl actually inhaled that amount. The striking thing about the human case he had described was the acute asthmatic attack, resembling ordinary asthma. Sir JOSEPH BARCKROFT pointed out the importance of the finding that you could have symptoms without pulmonary oedema.

Diagnosis of Blast and Gas Injuries

Prof. J. A. RYLE said that those who had had clinical experience of gas casualties should not find the differential diagnosis of blast injuries and gas poisoning difficult. The likelihood of

meeting a combination of gas and blast effects was probably small. The differential diagnosis would clearly be assisted by the history of the incident. A case of blast was obviously ill from the start. He would complain of pain and be breathless, and might have haemoptysis. The symptoms of gas poisoning, on the other hand, were of later onset and would be unlikely to include haemoptysis or pain, and in most cases of phosgene poisoning there would be a clear history of gas having been used. As regards treatment, rest was the first essential for both types of case. It was not known whether oxygen was beneficial in blast injuries of the lung. The clinical appearance of cases suggested that they should benefit from oxygen. He had seen the B.L.B. mask poorly tolerated, and wondered whether the old-fashioned nasal tube might be better in some cases. He favoured Prof. Shaw Dunn's view that the primary mechanism in pulmonary oedema was capillary damage. He did not think that the oedema was due to heart failure. To sum up: the differential diagnosis of pulmonary concussion and phosgene poisoning should rest on (1) history, (2) the appearance of the patient, and (3) symptoms and signs.

Dr. A. H. T. ROBB-SMITH agreed with Prof. Hadfield about the findings in cases of blast injury to the lungs. He thought that, on the whole, symptoms would not be confused with those of phosgene poisoning, as in pulmonary concussion symptoms developed almost immediately after the accident. Though it was difficult to assess the importance of pulmonary fat embolism, symptoms might closely resemble those of phosgene poisoning, for they came on about the same time, were characterized by severe pulmonary oedema, anoxaemia, and right heart failure. The treatment, however, was similar for both. He advocated a critical study of the pathogenesis of pulmonary oedema in fat embolism, as it might give some indication of the cause of phosgene oedema. In fat embolism the fat was non-irritative and the changes were consequent on vascular occlusion and local anoxaemia—factors which should be considered in phosgene poisoning. In cases of pulmonary oedema he had frequently observed haemoconcentration in the pulmonary circulation, despite the absence of gross change in the peripheral circulation. Haematocrit analysis of the blood in the two circulations might be profitable. He, like Dr. Osborn, had seen cases of so-called neurogenic pulmonary oedema; the condition had been produced experimentally in America by Farber.

Surgeon Rear-Admiral C. P. G. WAKELEY said that he had met with a rather different type of lung injury, in which the damage was certainly inflicted from without. Men so injured had been in the water near the place where depth charges were going off, and said that when the charge went off they could feel the "kick" from it. Some of them were brought in dead; others died afterwards. As a rule they showed no extreme damage of the chest. They often complained of abdominal pain, and often had haemoptysis, haematemesis, and diarrhoea. Post mortem the lungs showed the appearance of blast injuries. There were also injuries such as ruptured liver and other abdominal traumata.

Some Experimental Observations

Surgeon Lieut.-Commander FOSS said that he had carried out some experiments on the effect of adrenal cortical hormone in lewisite poisoning, but he had not examined the medulla of the suprarenals.

Prof. SHAW DUNN pointed out that the pressure in the blood vessels was not the only factor concerned in oedema; the rate of flow also played an important part. He was impressed with the importance of alternation in capillary dilatation. He understood that in the denervated lung no alternation in capillaries could be observed. This might be explained by the total blood supply to the lungs being much greater than in an intact lung. The alternation in bronchial activity was interesting, and if it was present in the human lung he wondered whether it should not be observed by radiologists during screening: he had not heard of any such alternation being observed in the human lung. Prof. J. H. GADDUM said that there was evidence that various forms of lung injury liberated histamine, and that it would be interesting to know

whether phosgene did this. Laqueur and Magnus had observed a primary fall of blood pressure after phosgene. This might be due to liberation of histamine.

Lung Haemorrhage

Dr. JOAN ROSS dealt in detail with carbon monoxide poisoning and the secondary pneumonia after blast injury to the lung. In compression the haemorrhages might be bilateral and symmetrical, were usually subpleural, and rib markings were usually seen. There was general congestion of the lungs and often oedema; Tardieu's spots were frequently seen, and there might be thrombosis of vessels. In concussion, on the other hand, the haemorrhages were always bilateral and symmetrical, and any subpleural haemorrhage was present as an extension from deeper areas. There was general congestion of the lungs, but Tardieu's spots and thrombosis of vessels were not found. Dr. Ross said she had not seen the massive hilar haemorrhages described by Dr. Osborn. In the typical case of blast injury to the lung there were free red cells in the alveoli, but the alveolar walls were normal and there was no oedema. These were the changes found at the early stages. In cases surviving longer the secondary changes which supervened were very like those seen in an ordinary lobar pneumonia. In the alveoli were red cells, fibrin, and mononuclear cells. It was very difficult to say what degree of fat embolism would prove fatal. Certainly fat embolism would not account for the haemorrhages. Colonel L. E. H. WHITBY asked what Dr. Ross considered to be the source of the fat in cases which had fat in the capillaries. Dr. Ross replied that in many such cases there were no fractures, and the fat was found only in the pulmonary capillaries and not elsewhere in the body. Its origin was unknown.

Technique of Investigating Action of Lung Irritants

Captain R. H. D. SHORT said that to distinguish between desquamation of the mucous membrane of bronchioles and spasm of bronchioles might not be easy, as both conditions might exist at the same time. The nuclei in desquamated epithelium would be pyknotic. In the experimental animal which had received trypan blue intravenously the mucous membrane would show diffuse cytoplasmic staining. In a series of rabbits exposed to 1 in 15,000 phosgene for fifteen minutes and killed at varying times afterwards collapse was a characteristic finding during the first six hours. Its distribution was lobular. The cavity of many alveoli was completely obliterated; in others it was reduced by more than 50%. It must therefore be decided whether this collapse was real or due to faulty technique. In rabbits in which the lungs had been removed without tying the trachea the degree of collapse described above had not been found, and it was therefore probably not the result of faulty technique. There were two possible causes for the collapse: spasm of the bronchioles, and obstruction of the bronchiolar lumen by desquamated epithelium. In rabbits and guinea-pigs given histamine intravenously examination of the lungs showed a very considerable degree of bronchiolar spasm. There was practically no collapse. It was probable that the alveolar collapse after exposure to phosgene was the result of a complete obstruction by desquamated epithelium of a bronchial lumen already reduced by spasm.

It had been found that alveolar exudate stained in a different manner according to the stage at which the animal had been killed after exposure. Before three to six hours the exudate stained blue with orange G and aniline blue; at about six hours it stained in alternating bands of yellow and blue; and, when fully developed, from twelve hours onwards, it stained yellow. That this was not due to the thickness of the section had been shown by staining sections of 5 and 20 μ , which stained in the same way. Protein films dried on slides and stained showed that solutions containing under 0.5% protein would stain blue; those between 1% and 0.5% had alternating bands of blue and yellow; and those over 1% would stain yellow. Solutions of the three plasma proteins revealed the same phenomenon, and films prepared from samples removed at intervals from plasma digested with a solution of trypsin behaved in the same way as a similar series in which boiled

trypsin solution was used. The staining reaction was not due to breaking down of protein. Though the basis of this staining reaction was obscure it appeared to provide a semi-quantitative method for estimating protein in exudates.

Surgeon Lieutenant R. M. CALDER, R.N.V.R., observed that the role of increased permeability of the lung capillaries in the production of pulmonary oedema had already been stressed. It was interesting to consider the other side of the picture—the mechanism for the absorption of fluid from the alveoli. That such a mechanism existed in a normal lung was an old observation. He had injected as much as 30 c.cm. of serum into a rabbit's trachea without killing it. After three hours about 30% of the injected fluid had disappeared, and 70% was away by eighteen hours. It was hoped to measure the absorption of fluid after phosgene in a similar way, but unfortunately most animals died after quite small injections when previously exposed to phosgene. Another difficulty was that one did not know how much fluid was lost by evaporation. Sir Joseph Barcroft calculated that on theoretical grounds a rabbit could evaporate as much as 25 c.cm. of water in a day. The main histological feature of such lungs was the intensity and speed of the phagocytic response. Within thirty minutes the alveoli and septa contained large numbers of mononuclear cells; where trypan blue had been added to the fluid these cells would nearly all contain granules of the dye. There was no dilatation of the lymphatics. This picture was in striking contrast to what was seen after phosgene, where the alveoli were practically free of cells in the stage of oedema and the lymphatics were widely dilated. The normal animal could remove from its lungs quantities of fluid larger than those found in animals dying from phosgene poisoning; this strongly suggested that after phosgene there must be some interference with the normal absorptive mechanism.

INSTRUCTION IN INJURIES OF THE LOCOMOTOR SYSTEM

Because of the need in both the E.M.S. and the Services for more surgeons with training and experience in the diagnosis and treatment of disabilities of the locomotor system, arrangements have been made for courses of instruction in the subject. Each course will extend over six weeks and will provide practical experience and instruction for the whole of that period. The surgeons attending the course will be divided into groups of not more than four, and each group will be attached to the wards and outpatient department of a senior surgeon experienced in this type of work. They will have charge of cases, carry out treatment, and receive practical demonstrations. They will also attend the work and teaching at neighbouring hospitals, fracture departments, and clinics.

The first course, which will start on September 15, at Alder Hey Hospital, near Liverpool, will be conducted by Mr. T. P. McMurray, Mr. B. L. McFarland, Mr. R. Watson-Jones, Mr. F. C. Dwyer, Mr. G. E. Thomas, and Mr. W. R. Mitchell. In addition to Alder Hey Emergency Hospital, the Royal Infirmary, the David Lewis Northern Hospital, and the Royal Southern Hospital, Liverpool, will be utilized. This course is designed for surgical specialists in the E.M.S. and fighting Services, who should be of the status of junior honorary staff or senior registrars. The number will be limited to sixteen, and applications should be sent as soon as possible to Dr. F. Murchie, Ministry of Health, Whitehall, London, S.W.1. Suitable accommodation will be arranged through Mr. T. P. McMurray in the neighbourhood of Alder Hey Hospital.

Before sending in their applications, medical officers in the E.M.S. should obtain through the medical superintendent or medical officer in charge of the hospital the permission of the hospital officer or group officer, and those accepted will be granted special leave to attend the course. Medical officers enrolled in Classes I, II, and IV will be continued on their existing contracts and will be refunded return travelling expenses from their present hospitals. For those enrolled in Class III, in addition to travelling expenses, a subsistence allowance is authorized to meet the cost of their billeting.

Nomenclature of Pituitary Principles

SIR,—The nomenclature of pituitary principles has been a fruitful source of discussion for some time past, and Dr. F. W. Landgrebe,¹ in a letter to *Nature*, has recently suggested that the general suffix *desmic* (from the Greek *δεσμός* meaning a bond or link) should be employed in the description of such substances. *Thyrotropic* becomes *thyrodesmic*, for example.

The multiplication of names in a terminology which is already overburdened can, I believe, lead only to still further trouble, and for this reason alone I cannot support Dr. Landgrebe's suggestion. Moreover, there seems to me no valid objection to retaining the suffix *tropic* now that it has become established in the literature, although in this respect I may not be in entire agreement with Prof. J. H. Burn² and Dr. A. S. Parkes,³ as well as with Dr. Landgrebe. Even if the etymology of the suffix *tropic* were definitely unsound, would it be worth the resulting confusion to attempt an amendment in conformity with what we now believe would have been considered good form by the Ancient Greeks? Prof. Burn² thought not, and Dr. Parkes³ would advocate nothing more than a slight change in spelling, although, it should be emphasized, this change in spelling connoted a definite change in meaning. In my opinion not only is a radical change in terminology undesirable on the grounds of convenience, but is etymologically unnecessary. The suffix *tropic* is ultimately based on the Greek verb *τρέπω*, which, as well as meaning "turn," can also mean "direct" or "change." Thus, on the basis of the origins of the word, a thyrotropic substance is not necessarily one which turns towards the thyroid gland; the term may also denote a substance which directs or changes the gland. The primary meaning is surely not the only one which can be applied to Greek roots in determining their significance in the English language. Every endocrinologist knows what is meant by the adjective "oestrogenic," but the captious logomach might insist that it primarily means "productive of gadflies"! Bacteriologists are not obliged to believe that "neurotropic" viruses are attracted towards the nervous system. Such viruses need do no more than manifest their presence by causing changes in nervous tissue. Therefore, I submit, the suffix *tropic*, in its application to pituitary substances, need not be discarded on the grounds of unworthy ancestors or undesirable relations.

Dr. A. S. Parkes³ has proposed that "thyrotropic" should be changed to "thyrotrophic" (*τροφός* = a wet nurse), as descriptive of a substance which induces hypertrophy of the thyroid gland, an action which presumably must be associated with increased nourishment of the tissue. The form *trophic* is correctly applicable to certain of the anterior lobe principles, and this form of the suffix was adopted in drawing up the report of the third International Conference on the Standardization of Hormones, held in August, 1939. Nevertheless, this conference, of which I was a member, agreed that both forms—*tropic* and *trophic*—might generally be used. The disadvantage of the form *trophic*, which is tending to become popular, is that some pituitary principles to which it is indiscriminately applied are not in reality *trophic*. Thus the terms "pancreatrophic," "medullotrophic," and "glycotrophic," which appear from time to time in the literature, are incorrect in that the active principles are not *trophic* under the implied conditions. Such difficulties can be avoided by retaining the original form of the suffix—*tropic*—as a general one descriptive of those pituitary substances which alter or change other glands, tissues, or metabolic conditions. This does not exclude the possibility of using, in appropriate cases, the form *trophic* as descriptive of pituitary principles which induce enlargement of other glands, although the more general term is, I believe, of greater importance. A more precise and refined terminology should await further development of our knowledge of the nature and action of these interesting pituitary substances.—I am, etc.,

Psychiatric Problems in Wartime: A Plea for Caution

SIR.—The interesting article by Captain R. F. Tredgold (July 26, p. 109), including as it does detailed observations upon psychotic states occurring in soldiers and their prognosis, together with a description of methods of treatment, gives cause for careful thought, and seems to prompt the question as to whether the present is the time to arrive at conclusions concerning problems of the deepest psychiatric significance.

While it may be of the utmost importance for psychiatrists carefully to record their observations and impressions of the clinical material with which they are called upon to deal in time of war, it is submitted that it will be some time before the opportunity for proper assimilation and mutual discussion of this experience and its implications for psychiatric theory can be obtained. For example, the present war came upon us before it was possible to arrive at scientifically based conclusions as to the precise value and sphere of beneficial application of the various forms of shock therapy. Service needs and the associated demand for simplicity and speed in application required the adoption of Raven-Penrose progressive matrices testing upon large numbers of men before there had been opportunity for full evaluation of this method. The investigation of amnesias, etc., under artificially induced states of narcosis—for example, injection of sodium amytal—prompts certain fundamental questions as to its bona fides from the psychopathological standpoint. Various methods of treatment require to be employed on empirical grounds for their symptomatic value alone and in the absence of suitable checks or controls. This may be admissible, but there appears to be a danger of hasty conclusions being formed from consideration merely of results. Further, when compared with the whole field of psychiatric case material, Service cases, though numerous and a formidable problem at the present time, are nevertheless a limited and selected group developing under artificial environmental conditions.

A case in point is the discussion concerning the nature of depression. It may be that the views expressed by Curran and Mallinson (March 1, p. 305) find a substantial measure of agreement among many psychiatrists, while others will continue to subscribe to the views of Ross and others touched upon in your leading article of July 5 (p. 21). But while it is admitted that in many instances the task of differentiating between "endogenous" and "reactive" depression constitutes a severe test of the psychiatrist's clinical acumen, surely there is danger in teaching the student that "distinction between neurosis and psychosis is at times convenient but without substance," when upon that distinction being made at as early a stage as possible in the development of the mental illness the mental well-being, future, and even the life of the patient may depend.—I am, etc.,

Liverpool, Aug. 7.

S. BARTON HALL.

Depressive States in the Soldier

SIR.—My attention has been drawn to Captain R. F. Tredgold's statement in his paper on the above subject (July 26, p. 109) that I "diagnosed the psychotic type [of depression] by the possession of insight." I hope and believe that it is by a mere *lapsus calami* that Captain Tredgold has credited me with this feat, however one interprets his pleasingly ambiguous phrase. To avoid any possible misunderstanding, however, please let me state that if he refers, as I assume, to the patient's insight I have never held or expressed the opinion which he seems to attribute to me. If the word "absence" were substituted for "possession" the sentence would at least be in harmony with my views so far as it goes.

I readily admit the difficulty of assessing insight, but I think most people recognize nowadays that psychiatry is a difficult specialty. I would also suggest, with respect, that in it, as in all other specialties, experience sometimes helps a little.—I am, etc.,

London, W.I, Aug. 3.

HENRY YELLOWLEES, M.D., F.R.C.P.

Air-raid Noises in Psychotherapy

SIR.—I was very interested in the article by Majors F. L. McLaughlin and W. M. Millar (August 2, p. 158), and I feel the authors are to be congratulated on the ingenuity which they have shown in getting gramophone records of the actual noises. I foresee great use being made of this type of therapy, especially

where the psychotherapist can control the volume of the noise at will while the patient is on the couch, and thus be able to work up "the dose." I hope it will be made possible for those doing this type of work to obtain similar records.

Just after the last war I was in a Ministry of Pensions hospital dealing with war neuroses, and I found the same difficulties—that is, that the men were noise-sensitive. The method which I used was in some way similar to those described in this article. I used to get the men to talk about their war experiences until they were very conversant with the anxiety-provoking incidents, and then I would get them to take a blanket out into a field at the back of the hospital (which was near a railway line), lie down, and relax, and when they saw a train approaching I suggested that they should close their eyes and take their minds back to their experiences in France and link up the emotions which they felt with the noise of the passing train. In a large number of cases the men had violent ab reactions coupled with an increase of memory for the actual happenings. After a few weeks of this treatment the majority were able to go into the town near by without suffering any ill effects from the noise of traffic, which had hitherto caused them acute anxiety.

In considering this type of therapy now, in view of my past experience, I cannot help but feel that much greater use should be made of transference relations between patient and therapist—first by adopting the attitude, "We together are facing these difficult situations which proved too much for you when you were alone"; and then, when the patient's self-confidence has been restored, a process of handing back to him the sense of his own responsibility as an adult and a competent member of society.—I am, etc.,

AUG. 5.

D. N. HARDCASTLE

SIR.—If it was Herodotus who declared that history repeats itself, he will find, if he reads the *B.M.J.* in Olympus, remarkable evidence in the article by Majors F. L. McLaughlin and W. M. Millar on the use of air-raid noises on the gramophone as a form of psychotherapy (August 2, p. 158). It certainly recalls with irresistible and entertaining vividness the medicament treating disease with his tom-tom and other cacophonies.

Although it is regrettably true that much of the practice of psychiatry at the present moment is empirical in character, one feels compelled to ask: Is there not a limit beyond which the descent into the extra-rational should not be pursued? If the answer is in the negative and the implication follows that symptomatic treatment is good enough, however achieved, I would like to suggest an improvement. It is that, on the conclusion of the gramophone treatment, a bellicose attitude should be stimulated in the patients by teaching them a war dance. In this the Gaumont British News, I am sure, could help from a selection of their films of Darkest Africa. Finally, the treatment could be properly rounded off by "conditioning" the patients to a record of Herr Hitler delivering one of his celebrated harangues. But that perhaps would be going too far!—I am, etc.,

London, W.1, Aug. 4.

FREDERICK DILLON.

Cardiac Arrest during Anaesthesia

SIR.—In reply to Drs. H. J. Brennan, J. W. Patterson, and Mr. F. R. Brown (August 2, p. 175), I can state that pure chloroform anaesthesia has not been used in any of the hospitals in the many parts of the country where I have worked. The forty cases represent the collected experience of over twenty years. Half of this time was spent in senior resident posts, where the proportion of serious emergency cases was very high. During this period my anaesthetists were for the most part hospital residents, and although I have not made statistics I do not think that the cases of cardiac arrest were unduly high on this account. In the case quoted in my paper the anaesthetic was administered by a professional anaesthetist of the highest attainments, whose skill I appreciate.

I suggest to Dr. Patterson that a surgeon with a penchant for the nerve-racking ordeal which the necessity for cardiac massage entails must be about as common as a general practitioner with a partiality for puerperal sepsis.

I should like to call attention to an error in my article; "Darling and Lane" should read "Starling and Lane" (July 19, p. 85). I am greatly indebted to Dr. Edwin Starling, who, in

pointing out my mistake, has sent me a most illuminating account of the first and successful recorded case of cardiac massage. I feel sure your readers will be interested to know that Sir Arbuthnot Lane conceived the idea of cardiac massage from watching animal experiments on the heart conducted by Dr. Starling's cousin, the late Prof. Ernest Starling, the eminent physiologist.—I am, etc.,

London, W.1, Aug. 2.

HAMILTON BAILEY.

Leadership in Medicine

SIR,—In two letters in your issue of August 2 there sounded a clear note of leadership of a kind for which the profession has been waiting. Sir Frederick Menzies denounced a policy of the Ministry of Health as only another example of "incompetence and unpreparedness," and it is surely time that the Ministry's instructions on the details of medical treatment be equally vigorously denounced as in varying degree superficial, unpractical, inaccurate, and peremptory. It is probable that the instructions have done little harm, because after any useful information has been abstracted they are frequently ignored. But a negative attitude is not enough, and this is one reason why Dr. Douglas Boyd's letter is welcome in calling on us to secure in every sphere a policy which unites personal responsibility with power. There will be great difficulties after the war, and as yet the profession merely exaggerates them and shudders. It is said that individuals will have no money to pay for medical attention; but is this certain? Will there be no money for clothes or food or amusement, and if so how are taxes to be raised to pay for State services? And where will all the national savings have gone? It is said, again, that the large teaching hospitals will require financial assistance from taxes, and that therefore they must come under Government control. The University Grants Committee illustrates that Government financial aid can be given with adequate safeguard of public money and no direct control and no curbing whatever of the grantees' initiative. It is said, also, that the existence of the National Health Insurance Act makes an extension of its methods inevitable, but this is not so, because the working of the Act could be altered so that payments are made for actual services rendered as in most forms of insurance, such as that of the Hospital Saving Association.
